Tobit models refer to regression models in which the range of the dependent variable is constrained in some way. In economics, such a model was first suggested in a pioneering work by Tobin (1958). He analyzed household expenditure on durable goods using a regression model which specifically took account of the fact that the expenditure (the dependent variable of his regression model) cannot be negative. Tobin called his model the model of limited dependent variables. It and its various generalizations are known popularly among economists as Tobit models, a phrase coined by Goldberger (1964), because of similarities to probit models. These models are also known as censored or truncated regression models. The model is called truncated if the observations outside a specified range are totally lost and censored if one can at least observe the exogenous variables. A more precise definition will be given later.

Censored and truncated regression models have been developed in other disciplines (notably biometrics and engineering) more or less independently of their development in econometrics. Biometricians use the model to analyze the survival time of a patient. Censoring or truncation occurs either if a patient is still alive at the last observation date or if he or she cannot be located. Similarly, engineers use the model to analyze the time to failure of material or of a machine or a system. These models are called survival models.¹ Sociologists and economists have also used survival models to analyze the duration of such phenomena as unemployment, welfare receipt, employment in a particular job, residing in a particular region, marriage, and the period of time between

births.\textsuperscript{2} Mathematically, survival models belong to the same general class of models as Tobit models and share certain characteristics. However, I will not discuss survival models in this survey because they possess special features of their own. See the survey by Heckman and Singer in this issue.

Between 1958, when Tobin's article appeared, and 1970, the Tobit model was used infrequently in econometric applications, but since the early 1970's numerous applications ranging over a wide area of economics have appeared and continue to appear. This phenomenon is due to a recent increase in the availability of micro sample survey data which the Tobit model analyzes well and to a recent advance in computer technology which has made estimation of large-scale Tobit models feasible. At the same time, many generalizations of the Tobit model and various estimation methods for these models have been proposed. In fact, models and estimation methods are now so numerous and diverse that it is difficult for econometricians to keep track of all the existing models and estimation methods and maintain a clear notion of their relative merits. Thus, it is now particularly useful to examine the current situation and prepare a unified summary and critical assessment of existing results.

I will try to accomplish this objective by means of classifying the diverse Tobit models into five basic types. (My review of the empirical literature suggests that roughly 95\% of the econometric applications of Tobit models fall into one of these five types.) While there are many ways to classify Tobit models, I have chosen to classify them according to the form of the likelihood function. This way seems to me to be the statistically most useful classification because a similarity in the likelihood function implies a similarity in the appropriate estimation and computation methods. It is interesting to note that two models which superficially seem to be very different from each other can be shown to belong to the same type when they are classified according to my scheme.

The remainder of the paper consists of two parts: part I deals with the Standard Tobit model (or Type 1 Tobit) and part II deals with the remaining four types of models. Basic estimation methods, which with a slight modification can be applied to any of the five types, are discussed at great length in part I. More specialized estimation methods are discussed in relevant passages throughout the paper. Each model is illustrated with a few empirical examples.

I should note the topics, in addition to the survival models mentioned above, which I do not discuss. I do not discuss disequilibrium models except for a few basic models which are examined in section 11.5. Some general references on disequilibrium models are cited there. Nor do I discuss the related topic of switching regression models. For a survey on these topics, the reader should

\textsuperscript{2}See Bartholomew (1973), Singer and Spilerman (1976), Tuma, Hanhan and Groeneveld (1979), Lancaster (1979), Tuma and Robins (1980), and Flinn and Heckman (1982).
consult Maddala (1980). I do not discuss Tobit models for panel data (individuals observed through time), except to mention a few papers in relevant passages, since they can be best discussed with survival models.

The econometrics text books which discuss Tobit models (with the relevant page numbers) are Goldberger (1964, pp. 251–255), Maddala (1977, pp. 162–171) and Judge, Griffiths, Hill and Lee (1980, pp. 609–616). Maddala (1983) gives a comprehensive discussion of Tobit models as well as qualitative response models and disequilibrium models.

I. Standard Tobit Model (Type 1 Tobit)

2. Definition of the model

Tobin (1958) noted that the observed relationship between household expenditures on a durable good and household incomes looks like fig. 1, where each dot represents an observation for a particular household. An important characteristic of the data is that there are several observations where the expenditure is zero. This feature destroys the linearity assumption so that the least squares method is clearly inappropriate. Should one fit a nonlinear relationship? First, one must determine a statistical model which can generate the kind of data depicted in fig. 1. In doing so the first fact one should recognize is that one cannot use any continuous density to explain the conditional distribution of expenditure given income because a continuous density is inconsistent with the fact that there are several observations at zero. Below I develop an elementary utility maximization model to explain the phenomenon in question.

![Fig. 1](image-url)
Define the symbols needed for the utility maximization model as follows:

\[ y = \text{a household's expenditure on a durable good}, \]
\[ y_0 = \text{the price of the cheapest available durable good}, \]
\[ z = \text{all the other expenditure}, \]
\[ x = \text{income}. \]

A household is assumed to maximize utility \( U(y, z) \) subject to the budget constraint \( y + z \leq x \) and the boundary constraint \( y \geq y_0 \) or \( y = 0 \). Suppose \( y^* \) is the solution of the maximization subject to \( y + z \leq x \) but ignoring the other constraint, and assume \( y^* = \beta_1 + \beta_2 x + u \), where \( u \) may be interpreted as the collection of all the unobservable variables which affect the utility function. Then, the solution to the original problem, denoted by \( y \), can be defined by

\[
y = \begin{cases} 
y^* & \text{if } y^* > y_0, \\
0 & \text{or } y_0 & \text{if } y^* \leq y_0.
\end{cases}
\]

If we assume that \( u \) is a random variable and that \( y_0 \) varies with households but is assumed known, this model will generate data like fig. 1. We can write the likelihood function for \( n \) independent observations from the model (1) as

\[
L = \prod_0 F_i(y_0) \prod f_i(y_i),
\]

where \( F_i \) and \( f_i \) are the distribution and density function respectively of \( y_i^* \), \( \prod_0 \) means the product over those \( i \) for which \( y_i^* \leq y_0 \), and \( \prod_1 \) means the product over those \( i \) for which \( y_i^* > y_0 \). Note that the actual value of \( y \) when \( y^* \leq y_0 \) has no effect on the likelihood function. Therefore, the second line of eq. (1) may be changed to the statement 'if \( y^* \leq y_0 \), one merely observes that fact'.

The model originally proposed by Tobin (1958) is essentially the same as the above except that he specifically assumes \( y^* \) to be normally distributed and assumes \( y_0 \) to be the same for all households. We define the Standard Tobit model (or Type 1 Tobit) as follows:

\[
y_i^* = x_i' \beta + u_i, \quad i = 1, 2, \ldots, n, \]

\[
y_i = \begin{cases} 
y_i^* & \text{if } y_i^* > 0, \\
0 & \text{if } y_i^* \leq 0.
\end{cases}
\]

where \( \{u_i\} \) are assumed to be i.i.d. drawings from \( N(0, \sigma^2) \). It is assumed that \( \{y_i\} \) and \( \{x_i\} \) are observed for \( i = 1, 2, \ldots, n \), but \( \{y_i^*\} \) are unobserved if \( y_i^* \leq 0 \). Defining \( X \) to be the \( n \times K \) matrix whose \( i \)th row is \( x_i' \), we assume that
lim_{n \to \infty} n^{-1}X'X is positive definite. In the Tobit model one needs to distinguish the vectors and matrices of positive observations from the vectors and matrices of all the observations; the latter appear in bold print.

Note that \( y_i^* > 0 \) and \( y_i^* \leq 0 \) in (4) may be changed to \( y_i^* > y_0 \) and \( y_i^* \leq y_0 \) without essentially changing the model, whether \( y_0 \) is known or unknown, since \( y_0 \) can be absorbed into the constant term of the regression. If, however, \( y_{0i} \) changes with \( i \) and is known for every \( i \), the model is slightly changed because the resulting model would be essentially equivalent to the model defined by (3) and (4) where one of the elements of \( \beta \) other than the constant term is known. The model where \( y_{0i} \) changes with \( i \) and is unknown is not generally estimable.

The likelihood function of the Standard Tobit model is given by

\[
L = \prod_{i} \left[ 1 - \Phi(x_i'\beta/\sigma) \right] \prod_{i} \sigma^{-1} \phi\left( (y_i - x_i'\beta)/\sigma \right),
\]

where \( \Phi \) and \( \phi \) are the distribution and density function respectively of the standard normal variable.

The Tobit model belongs to what is sometimes known as the censored regression model. In contrast, if one observes neither \( y_i \) nor \( x_i \) when \( y_i^* \leq 0 \), the model is known as a truncated regression model. The likelihood function of the truncated version of the Tobit model can be written as

\[
L = \prod_{i} \Phi(x_i'\beta/\alpha)^{-1} \alpha^{-1} \phi\left( (y_i - x_i'\beta)/\alpha \right).
\]

Henceforth, the Standard Tobit model refers to the model defined by (3) and (4), namely a censored regression model, and the model whose likelihood function is given by (6) will be called the truncated Standard Tobit model.

3. Empirical examples

Tobin (1958) obtained the maximum likelihood estimates of his model applied to data on 735 non-farm households obtained from Surveys of Consumer Finances. The dependent variable of his estimated model was actually the ratio of total durable goods expenditure to disposable income and the independent variables were the age of the head of the household and the ratio of liquid assets to disposable income.

Since then, and especially since the early 1970’s, numerous applications of the Standard Tobit model have appeared in economic journals, encompassing a wide range of fields in economics. I will present below a brief list of recent representative papers, with a description of the dependent variable and the main independent variables. In all the papers except Kotlikoff, who uses a two-step estimation method which I will discuss later, the method of estimation is maximum likelihood.
Adams (1980)
y: Inheritance.
\[ x: \text{Income, marital status, number of children.} \]

Ashenfelter and Ham (1979)
y: Ratio of unemployed hours to employed hours.
\[ x: \text{Years of schooling, working experience.} \]

Fair (1978)
y: Number of extra-marital affairs.
\[ x: \text{Sex, age, number of years married, number of children, education, occupation, degree of religiousness.} \]

Keeley, Robins, Spiegelman and West (1978)
y: Hours worked after a Negative Income Tax program.
\[ x: \text{Pre-program hours worked, change in the wage rate, family characteristics.} \]

Kotlikoff (1979)

y: Number of arrests (or convictions) per month after release from prison.
\[ x: \text{Accumulated work release funds, number of months after release until first job, wage rate after release, age, race, drug use.} \]
4. Properties of estimators under standard assumptions

In this section I will discuss the properties of various estimators of the Tobit model under the assumptions of the model. The estimators I consider are probit maximum likelihood (ML), least squares (LS), Heckman's two-step, nonlinear least squares (NLLS), nonlinear weighted least squares (NLWLS), and the Tobit ML.

4.1. Probit maximum likelihood estimator

The Tobit likelihood function (5) can be trivially rewritten as follows:

\[ L = \prod_{i=1}^{n} \left[1 - \Phi(x_i^* / \sigma)\right] \prod_{i=1}^{n} \Phi(x_i^* / \sigma) \times \prod_{i=1}^{n} \Phi(x_i^* / \sigma)^{-1} \sigma^{-1}\phi\left(\frac{y_i - x_i^* / \sigma}{\sigma}\right). \]  

Then, the first two products of the right-hand side of (7) constitute the likelihood function of a probit model, and the last product is the likelihood function of the truncated Tobit model as given in (6). The probit ML estimator of \( \alpha = \beta / \sigma \), denoted \( \hat{\alpha} \), is obtained by maximizing the logarithm of the first two products. The maximization must be done by an iteration scheme such as Newton–Raphson or the method of scoring [see Amemiya (1981b, p. 1496)], where convergence is assured by the global concavity of the logarithmic likelihood function.3

Note that one can only estimate the ratio \( \beta / \sigma \) by this method and not \( \beta \) or \( \sigma \) separately. Since the estimator ignores a part of the likelihood function that involves \( \beta \) and \( \sigma \), it is not fully efficient. This loss of efficiency is not surprising when one realizes that the estimator uses only the sign of \( y_i^* \), ignoring its numerical value even when it is observed.

The probit MLE is consistent and one can show by a standard method [see, for example, Amemiya (1978, p. 1196)] that

\[ \hat{\alpha} - \alpha = \left(XD_0X\right)^{-1}X'D_0D_0^{-1}(w - Ew), \]

3Let \( \log L(\theta) \) be a logarithmic likelihood function of a parameter vector \( \theta \) in general. Then, global concavity means that \( \partial^2 \log L / \partial \theta \partial \theta' \) is negative definite over the whole parameter space. Let \( \hat{\theta} \) be the MLE. Then, by a Taylor expansion we have

\[ \log L(\theta) = \log L(\hat{\theta}) + \frac{1}{2} (\theta - \hat{\theta})' (\partial^2 \log L / \partial \theta \partial \theta') (\theta - \hat{\theta}), \]

where we have used the fact that \( \partial \log L / \partial \theta \) evaluated at \( \hat{\theta} \) is zero by definition of the MLE, and \( \partial^2 \log L / \partial \theta \partial \theta' \) is evaluated at a point between \( \theta \) and \( \hat{\theta} \). Therefore, global concavity implies \( \log L(\theta) < \log L(\hat{\theta}) \) for any \( \theta \neq \hat{\theta} \).
where $D_0$ is the $n \times n$ diagonal matrix whose $i$th element is $\phi(x'_i\alpha)$, $D_1$ is the $n \times n$ diagonal matrix whose $i$th element is $\Phi(x'_i\alpha)^{-1}[1 - \Phi(x'_i\alpha)]^{-1}\phi(x'_i\alpha)^2$ and $\omega$ is the $n$-vector whose $i$th element $\omega_i$ is defined by

$$w_i = 1 \quad \text{if} \quad y_i^* > 0,$$

$$= 0 \quad \text{if} \quad y_i^* \leq 0. \quad (9)$$

Note that the $i$th element of $E\omega$ is equal to $\Phi(x'_i\alpha)$. The symbol $\overset{\sim}{=}$ means that both sides have the same asymptotic distribution. Therefore, $\hat{\alpha}$ is asymptotically normal with mean $\alpha$ and asymptotic variance-covariance matrix given by

$$V\hat{\alpha} = (X'D_1X)^{-1}. \quad (10)$$

4.2. Least squares estimator

From fig. 1 it is clear that the least square regression of expenditure on income using all the observations including zero expenditures yields biased estimates. Though it is not so clear from the figure, the least squares regression using only the positive expenditures also yields biased estimates. These facts can be mathematically demonstrated as follows.

First, I will consider the regression using only positive observations of $y_i$. We get from (3) and (4)

$$E(y_i|y_i > 0) = x'_i\beta + E(u_i|u_i > -x'_i\beta). \quad (11)$$

The last term of the right-hand side of (11) is generally non-zero (even without assuming $u_i$ is normal). This implies the biasedness of the LS estimator using positive observations on $y_i$ under more general models than the Standard Tobit model. When we assume normality of $u_i$ as in the Tobit model, (11) can be shown by straightforward integration to be

$$E(y_i|y_i > 0) = x'_i\beta + \sigma\lambda(x'_i\beta/\sigma), \quad (12)$$

where $\lambda(z) = \phi(z)/\Phi(z)$. As I will show below, this equation plays a key role in the derivation of Heckman's two-step, NLLS, and NLWLS estimators.

---

4 More precisely, $\overset{\sim}{=}$ means in this particular case that $\sqrt{n}$ times both sides of the equation have the same limit distribution.

5 $\lambda(\cdot)$ is known as the hazard rate and its reciprocal is known as Mills’ ratio. Tobin (1958) gives a figure which shows that $\lambda(z)$ can be closely approximated by a linear function of $z$ for $-1 < z < 5$. Johnson and Kotz (1970, p. 278f.) give various expansions of Mills’ ratio.
Eq. (12) clearly indicates that the LS estimator of $\beta$ is biased and inconsistent, but the direction and magnitude of the bias or inconsistency cannot be shown without further assumptions. Goldberger (1981) evaluated the asymptotic bias (the probability limit minus the true value) assuming that the elements of $x_i$, except the first element which is assumed to be a constant, are normally distributed. More specifically, Goldberger rewrites (3) as

$$y_i^* = \beta_0 + \bar{x}_i'\beta_1 + u_i,$$

and assumes $\bar{x}_i \sim N(0, \Sigma)$ and is distributed independently of $u_i$. (Here, the assumption of zero mean involves no loss of generality since a non-zero mean can be absorbed into $\beta_0$.) Under this assumption he obtains

$$\text{plim} \beta_1 = \left[ \frac{1 - \gamma}{1 - \rho^2 \gamma} \right] \beta_1,$$  \hspace{1cm} (14)

where $\gamma = \sigma^2 \lambda(\beta_0/\sigma_x) [\beta_0 + \sigma_x \lambda(\beta_0/\sigma_x)]$ and $\rho^2 = \sigma^2 \lambda^2 + \beta_1^2 \Sigma \beta_1$. It can be shown that $0 < \gamma < 1$ and $0 < \rho^2 < 1$; therefore, (14) shows that $\beta_1$ shrinks $\beta_1$ toward zero. It is remarkable that the degree of shrinkage is uniform in all the elements of $\beta_1$. However, the result may not hold if $\bar{x}_i$ is not normal; Goldberger gives a nonnormal example where $\beta_1 = (1,1)'$ and $\text{plim} \beta_1 = (1.111,0.887)'$.

Next, I will consider the regression using all the observations of $y_i$, both positive and zero. To see that the least squares estimator is also biased in this case, one should look at the unconditional mean of $y_i$,

$$E y_i = \Phi(x_i'\beta/\sigma) \cdot x_i'\beta + \sigma \phi(x_i'\beta/\sigma).$$ \hspace{1cm} (15)

Writing (3) again as (13) and using the same assumptions as Goldberger, Greene (1981) showed

$$\text{plim} \beta_1 = \Phi(\beta_0/\sigma_x) \cdot \beta_1,$$ \hspace{1cm} (16)

where $\beta_1$ is the LS estimator of $\beta_1$ in the regression of $y_i$ on $x_i$ using all the observations. This result is even more remarkable than (14) because it implies that $(n/n_1) \cdot \hat{\beta}_1$ is a consistent estimator of $\beta_1$, where $n_1$ is the number of positive observations of $y_i$. A simple consistent estimator of $\beta_0$ can be similarly obtained. Greene (1983) gives the asymptotic variances of these estimators. Unfortunately, however, one cannot confidently use this estimator without knowing its properties when the true distribution of $\bar{x}_i$ is not normal.

Chung and Goldberger (1982) generalize the results of Goldberger (1981) and Greene (1981) to the case where $y^*$ and $\bar{x}$ are not necessarily jointly normal but $E(\bar{x}|y^*)$ is linear in $y^*$. 

9
4.3. Heckman's two-step estimator

Heckman (1976), following a suggestion of Gronau (1974), proposed a two-step estimator in a two-equation generalization of the Tobit model. I classify this model as the Type 3 Tobit model and discuss it later. But his estimator can also be used in the Standard Tobit model, as well as in more complex Tobit models, with only a minor adjustment. I will discuss the estimator in the context of the Standard Tobit model because all the basic features of the method can be revealed in this model. However, one should keep in mind that since the method requires the computation of the probit MLE, which itself requires an iterative method, the computational advantage of the method over the Tobit MLE (which is more efficient) is not as great in the Standard Tobit model as it is in more complex Tobit models.

To explain this estimator, it is useful to rewrite (12) as

\[ y_i = x'_i \beta + \sigma \lambda (x'_i \alpha) + \epsilon_i, \quad \text{for } i \text{ such that } y_i > 0, \]

(17)

where I have written \( \alpha \equiv \beta/\sigma \) as before and \( \epsilon_i = y_i - E(y_i | y_i > 0) \) so that \( E \epsilon_i = 0 \). The variance of \( \epsilon_i \) is given by

\[ V \epsilon_i = \sigma^2 - \sigma^2 x'_i \alpha \lambda (x'_i \alpha) - \sigma^2 \lambda (x'_i \alpha)^2. \]

(18)

Thus, (17) is a heteroscedastic nonlinear regression model with \( n_i \) observations. The estimation method Heckman proposed consists of the following two steps: (1) Estimate \( \alpha \) by the probit MLE (denoted \( \hat{\alpha} \)) defined earlier. (2) Regress \( y_i \) on \( x_i \) and \( \lambda (x'_i \hat{\alpha}) \) by least squares using only the positive observations on \( y_i \).

To facilitate further the discussion of Heckman's estimator, rewrite (17) again as

\[ y_i = x'_i \beta + \sigma \lambda (x'_i \alpha) + \epsilon_i + \eta_i, \quad \text{for } i \text{ such that } y_i > 0, \]

(19)

where \( \eta_i = \sigma \lambda (x'_i \alpha) - \lambda (x'_i \hat{\alpha}) \). I write (19) in vector notation as

\[ y = X\beta + \sigma \hat{\lambda} + \epsilon + \eta, \]

(20)

where the vectors \( y, \hat{\lambda}, \epsilon \) and \( \eta \) have \( n_i \) elements and the matrix \( X \) has \( n_i \) rows, corresponding to the positive observations of \( y_i \). I further rewrite (20) as

\[ y = \tilde{Z} \gamma + \epsilon + \eta, \]

(21)

where I have defined \( \tilde{Z} = (X, \hat{\lambda}) \) and \( \gamma = (\beta', \sigma) \). Then, Heckman's two-step
The estimator of $\gamma$ is defined as

$$\hat{\gamma} = (\hat{Z}'\hat{Z})^{-1}\hat{Z}'y.$$  \hfill (22)

The consistency of $\hat{\gamma}$ follows easily from (21) and (22). I will derive its asymptotic distribution for the sake of completeness, though the result is a special case of Heckman's result (1979). From (21) and (22) we have

$$\sqrt{n_1}(\hat{\gamma} - \gamma) = (n_1^{-1/2}\hat{Z}'\hat{Z})^{-1}\left(n_1^{-1/2}\hat{Z}'\epsilon + n_1^{-1/2}\hat{Z}'\eta\right).$$  \hfill (23)

Since the probit MLE $\hat{\alpha}$ is consistent, we have

$$\lim_{n_1 \to \infty} n_1^{-1/2}\hat{Z}'\epsilon = \lim_{n_1 \to \infty} n_1^{-1/2}Z'\epsilon,$$  \hfill (24)

where $Z = (X, \lambda)$. It is easy to prove

$$n_1^{-1/2}\hat{Z}'\epsilon \rightarrow N(0, \sigma^2\lim n_1^{-1}Z'SZ),$$  \hfill (25)

where $\sigma^2S \equiv E\epsilon\epsilon'$ is the $n_1 \times n_1$ diagonal matrix whose diagonal elements are $V\epsilon_i$ given in (18). We have by Taylor expansion of $\lambda(x'\hat{a})$ around $\lambda(x'\alpha)$,

$$\eta \equiv -\sigma\left(\partial\lambda/\partial\alpha'\right)(\hat{\alpha} - \alpha).$$  \hfill (26)

Using (26) and (8) we can prove

$$n_1^{-1/2}\hat{Z}'\eta \rightarrow N\left[0, \sigma^2Z'(I - \Sigma)X(X'D_1X)^{-1}X'(I - \Sigma)Z\right],$$  \hfill (27)

where $D_1$ was defined after (8). Next, note that $\epsilon$ and $\eta$ are uncorrelated because $\eta$ is asymptotically a linear function of $w$ on account of (8) and (26) and $\epsilon$ and $w$ are uncorrelated. Therefore, from (23), (24), (25) and (27) we finally conclude that $\hat{\gamma}$ is asymptotically normal with mean $\gamma$ and the asymptotic variance–covariance matrix given by

$$V\hat{\gamma} = \sigma^2(Z'Z)^{-1}Z\left[\Sigma + \sigma^2(I - \Sigma)X(X'D_1X)^{-1}X'(I - \Sigma)\right]Z(Z'Z)^{-1}.$$  \hfill (28)

The above expression may be consistently estimated either by replacing the unknown parameters by their consistent estimates or by $(Z'Z)^{-1}Z'AZ(Z'Z)^{-1}$ where $A$ is the diagonal matrix whose $i$th diagonal element is $[y_i - x_i'\hat{B} - \hat{\alpha}(x_i'\hat{a})]^2$, following the idea of White (1980).
Note that the second matrix within the square bracket above arises because \( \lambda \) had to be estimated. If \( \lambda \) were known, one could apply least squares directly to (17) and the exact variance–covariance matrix would be \( \sigma^2(Z'Z)^{-1}Z'\Sigma Z(Z'Z)^{-1} \).

Heckman's two-step estimator uses the conditional mean of \( y_i \) given in (12). A similar procedure can also be applied to the unconditional mean of \( y_i \) given by (15). That is to say, one can regress all the observations of \( y_i \) including zeros on \( \Phi x_i \) and \( \Phi \) after replacing the \( \alpha \) that appears in the argument of \( \Phi \) and \( \phi \) by the probit MLE \( \hat{\alpha} \). In the same way as we derived (17) and (19) from (12), we can derive the following two equations from (15):

\[
y_i = \Phi(x_i'\alpha)[x_i'\beta + \sigma \lambda(x_i'\alpha)] + \delta_i, \quad (29)
\]

and

\[
y_i = \Phi(x_i'\hat{\alpha})[x_i'\beta + \sigma \lambda(x_i'\hat{\alpha})] + \delta_i + \xi_i, \quad (30)
\]

where \( \delta_i = \gamma_i - E\gamma_i \) and \( \xi_i = [\Phi(x_i'\alpha) - \Phi(x_i'\hat{\alpha})]x_i\beta + \sigma[\phi(x_i'\alpha) - \phi(x_i'\hat{\alpha})] \). A vector equation comparable to (21) is

\[
y = \hat{D}\hat{Z}\gamma + \delta + \xi. \quad (31)
\]

where \( \hat{D} \) is the \( n \times n \) diagonal matrix whose \( i \)th element is \( \Phi(x_i'\hat{\alpha}) \). Note that the vectors and matrices appear in bold print because they consist of \( n \) elements or rows. The two-step estimator of \( \gamma \) based on all the observations, denoted \( \hat{\gamma} \), is defined as

\[
\hat{\gamma} = (\hat{Z}'\hat{D}^2\hat{Z})^{-1}\hat{Z}'\hat{D}y. \quad (32)
\]

The estimator can easily be shown to be consistent. To derive its asymptotic distribution, we obtain from (31) and (32)

\[
\sqrt{n}(\hat{\gamma} - \gamma) = (n^{-1}\hat{D}^2\hat{Z})^{-1}(n^{-1/2}\hat{D}\delta + n^{-1/2}\hat{D}\xi). \quad (33)
\]

Here, unlike the previous case, an interesting fact emerges: by expanding \( \Phi(x_i'\hat{\alpha}) \) and \( \phi(x_i'\hat{\alpha}) \) in Taylor series around \( x_i'\alpha \) one can show \( \xi_i = O(n^{-1}) \). Therefore,

\[
\text{plim} n^{-1/2}\hat{Z}'\hat{D}\xi = 0. \quad (34)
\]

Corresponding to (24), we have

\[
\text{plim} n^{-1/2}\hat{Z}'\hat{D}^2\hat{Z} = \lim n^{-1}Z'D^2Z, \quad (35)
\]

\( ^6 \)This was suggested by Wales and Woodland (1980).
where $D$ is obtained from $\hat{D}$ by replacing $\hat{a}$ with $a$. Corresponding to (25), we have

$$n^{-1/2} \hat{Z} \hat{D} \delta \rightarrow N(0, \sigma^2 \lim n^{-1} Z'D^2 \Omega Z'),$$

(36)

where $\sigma^2 \Omega = E \delta \delta'$ is the $n \times n$ diagonal matrix whose $i$th element is $\sigma^2 \Phi(x_0'\alpha)((x_0'\alpha)^2 + x_0'\alpha \lambda(x_0'\alpha) + 1 - \Phi(x_0'\alpha)[x_0'\alpha + \lambda(x_0'\alpha)])^2$. Therefore, from (33) - (36), we conclude that $\gamma$ is asymptotically normal with mean $\gamma$ and the asymptotic variance–covariance matrix given by

$$V \hat{\gamma} = \sigma^2 (Z'D^2Z)^{-1} Z'D^2 \Omega Z(Z'D^2Z)^{-1}.$$  

(37)

Which of the two estimators $\hat{\gamma}$ and $\tilde{\gamma}$ is preferred? Unfortunately, the difference of the two matrices given by (28) and (37) is generally neither positive definite nor negative definite. Thus, an answer to the above question depends on parameter values.

Both (21) and (31) represent heteroscedastic regression models. Therefore, one can obtain asymptotically more efficient estimators by using weighted least squares (WLS) in the second step of the procedure for obtaining $\hat{\gamma}$ and $\tilde{\gamma}$. In doing so, one must use a consistent estimate of the asymptotic variance–covariance matrix of $\varepsilon + \eta$ for the case of (21) and of $\delta + \xi$ for the case of (31). Since these matrices depend on $\gamma$, an initial consistent estimate of $\gamma$ (say, $\hat{\gamma}$ or $\tilde{\gamma}$) is needed to obtain the WLS estimators. I call these WLS estimators $\hat{\gamma}_w$ and $\tilde{\gamma}_w$, respectively. It can be shown that they are consistent and asymptotically normal with the asymptotic variance–covariance matrices given by

$$V \hat{\gamma}_w = \sigma^2 \left( Z' \left[ \Sigma + (I - \Sigma) X'(X'D_lX)^{-1} X'(I - \Sigma) \right]^{-1} Z \right)^{-1},$$

(38)

and

$$V \tilde{\gamma}_w = \sigma^2 (Z'D^2Z)^{-1}.$$  

(39)

Again, one cannot make a definite comparison between two matrices.

4.4. Nonlinear least squares and nonlinear weighted least squares estimators

In this subsection I will consider four estimators: the NLLS and NLWLS estimators applied to (17), denoted $\hat{\gamma}_N$ and $\tilde{\gamma}_N$, respectively, and the NLLS and NLWLS estimators applied to (29), denoted $\hat{\gamma}_N$ and $\tilde{\gamma}_N$.

All these estimators are consistent and their asymptotic distributions can be obtained straightforwardly by noting that all the results of a linear regression

\[7\] To the best of my knowledge, this result was first obtained by Stapleton and Young (1981).
model hold asymptotically for a nonlinear regression model if we treat the derivative of the nonlinear regression function with respect to the parameter vector as the regression matrix. In this way one can show the interesting fact that $\hat{\gamma}_N$ and $\hat{\gamma}_{NW}$ have the same asymptotic distributions as $\hat{\gamma}$ and $\hat{\gamma}_W$ respectively. One can also show that $\hat{\gamma}_N$ and $\hat{\gamma}_{NW}$ are asymptotically normal with mean $\gamma$ and with their respective asymptotic variance–covariance matrices given by

$$\sqrt{\gamma}_N = \sigma^2 (S'S)^{-1} S' \Sigma S (S'S)^{-1},$$

(40)

and

$$\sqrt{\gamma}_{NW} = \sigma^2 (S'S^{-1}S)^{-1},$$

(41)

where $S = (\Sigma X, D_2 \lambda)$, with $D_2$ is the $n_1 \times n_1$ diagonal matrix whose $i$th element is $1 + (x_i' \alpha)^2 + x_i' \alpha_i (x_i' \alpha)$. One cannot make a definite comparison either between (28) and (40) or between (38) and (41).

In the two-step methods defining $\hat{\gamma}$ and $\hat{\gamma}$ and their generalizations $\hat{\gamma}_W$ and $\hat{\gamma}_{W}$, one can naturally define an iteration procedure by repeating the two steps. For example, having obtained $\hat{\gamma}$, one can obtain a new estimate of $\alpha$, insert it into the argument of $\lambda$, and apply least squares again to eq. (17). The procedure is to be repeated until a sequence of estimates of $\alpha$ thus obtained converges. In the iteration starting from $\hat{\gamma}_W$, one uses the $m$th round estimate of $\gamma$ not only to evaluate $h$ but also to estimate the variance–covariance matrix of the error term for the purpose of obtaining the $(m + 1)$st round estimate. Iterations starting from $\hat{\gamma}$ and $\hat{\gamma}_W$ can be similarly defined but are probably not worthwhile because $\hat{\gamma}$ and $\hat{\gamma}_W$ are asymptotically equivalent to $\hat{\gamma}_N$ and $\hat{\gamma}_{NW}$ as I have indicated above. The estimators $(\hat{\gamma}_N, \hat{\gamma}_{NW}, \hat{\gamma}_N, \hat{\gamma}_{NW})$ are clearly stationary values of the iterations starting from $(\hat{\gamma}, \hat{\gamma}_W, \hat{\gamma}, \hat{\gamma}_W)$. However, they may not necessarily be the converging values.

A simulation study by Wales and Woodland (1980) based on only one replication with sample sizes of 1000 and 5000 showed that $\hat{\gamma}_N$ is distinctly inferior to the MLE and is rather unsatisfactory.

4.5. Tobit maximum likelihood estimator

The likelihood function of the Tobit model was given in (5), from which we obtain the logarithmic likelihood function

$$\log L = \sum_0 \log \left[1 - \Phi \left( x_i' \alpha / \sigma \right) \right] - \frac{n_1}{2} \log \sigma^2 - \frac{1}{2\sigma^2} \sum_1 (y_i - x_i' \beta)^2.$$  

(42)

See Amemiya (1981a). Hartley (1976b) proved the asymptotic normality of $\hat{\gamma}_N$ and $\hat{\gamma}_{NW}$ and that they are asymptotically not as efficient as the MLE.

The asymptotic equivalence of $\hat{\gamma}_N$ and $\hat{\gamma}$ was proved by Stapleton and Young (1981).
The derivatives are given by

\[
\frac{\partial \log L}{\partial \beta} = -\frac{1}{\sigma} \sum_{i=0}^{n} \frac{\phi(x_i'\beta/\sigma)x_i}{1 - \Phi(x_i'\beta/\sigma)} + \frac{1}{\sigma^2} \sum_{i=1}^{n} (y_i - x_i'\beta)x_i,
\]

and

\[
\frac{\partial \log L}{\partial \sigma^2} = \frac{1}{2\sigma^3} \sum_{i=0}^{n} x_i'\beta\phi(x_i'\beta/\sigma) - \frac{n_i}{2\sigma^2} + \frac{1}{2\sigma^4} \sum_{i=1}^{n} (y_i - x_i'\beta)^2.
\]

Amemiya (1973) proved that the Tobit MLE is strongly consistent and asymptotically normal with the asymptotic variance–covariance matrix equal to \(-\sigma^2 \log L/\partial \theta \partial \theta'\)^{-1}, where \(\theta = (\beta', \sigma^2)^\prime\).

The Tobit MLE is defined as a solution of the equations obtained by equating the partial derivatives (43) and (44) to zero. The equations are nonlinear in the parameters and hence must be solved iteratively. However, Olsen (1978a) proved the global concavity of \(\log L\) in the Tobit model in terms of the transformed parameters \(\alpha = \beta/\sigma\) and \(h = \sigma^{-1}\), which implies that a standard iterative method such as Newton–Raphson or the method of scoring always converges to the global maximum of \(\log L\). The \(\log L\) in terms of the new parameters can be written as

\[
\log L = \sum_{i=0}^{n} \log[1 - \Phi(x_i'\alpha)] + n_1 \log h - \frac{1}{2} \sum_{i=1}^{n} (y_i - x_i'\alpha)^2,
\]

from which Olsen obtains

\[
\begin{bmatrix}
\frac{\partial^2 \log L}{\partial \alpha \partial \alpha'} & \frac{\partial^2 \log L}{\partial \alpha \partial h} \\
\frac{\partial^2 \log L}{\partial h \partial \alpha'} & \frac{\partial^2 \log L}{\partial h^2}
\end{bmatrix}
- \begin{bmatrix}
\sum_{i=0}^{n} \frac{\phi_i}{1 - \Phi_i} \left(x_i'\alpha - \frac{\phi_i}{1 - \Phi_i}\right)x_i'x_i' & 0 \\
0 & -\frac{n_i}{h^2}
\end{bmatrix}
\]

\[
+ \begin{bmatrix}
-\sum_{i=1}^{n} x_i x_i' & \sum_{i=1}^{n} x_i y_i \\
\sum_{i=1}^{n} y_i x_i' & -\sum_{i=1}^{n} y_i^2
\end{bmatrix}.
\]

\[\text{10} \text{The formulae for the second derivatives are given in Amemiya (1973, p. 1000). The asymptotic variance–covariance matrix may also be estimated by } -\frac{E(\partial^2 \log L/\partial \theta \partial \theta')^{-1}, \text{ which is given in Amemiya (1973, p. 1007).}
\]

\[\text{11} \text{Amemiya (1973) showed that the Tobit likelihood function is not globally concave with respect to the original parameters } \beta \text{ and } \sigma^2.\]
where $\phi_i = \phi(x_i'\alpha)$ and $\Phi_i = \Phi(x_i'\alpha)$. But, $x_i'\alpha - [1 - \Phi_i(x_i'\alpha)]^{-1}\phi_i(x_i'\alpha) < 0$. Therefore, the right-hand side of (46) is the sum of two negative-definite matrices and hence is negative definite.

Even though convergence is assured by global concavity, it is a good idea to start an iteration with a good estimator because it will improve the speed of convergence. Tobin (1958) used the following simple estimator based on a linear approximation of the reciprocal of Mills’ ratio to start his iteration for obtaining the MLE: By equating the right-hand side of (43) to zero, we obtain

$$-\sigma \sum_0 \frac{\Phi_i}{(1 - \Phi_i)} x_i + \sum_1 (y_i - x_i'\beta) x_i = 0. \quad (47)$$

If we premultiply (47) by $\beta'(2\sigma^2)$ and add it to the equation obtained by setting (44) equal to zero, we get

$$\sigma^2 = n_i^{-1} \sum_1 (y_i - x_i'\beta)y_i. \quad (48)$$

Approximate $(1 - \Phi_i)^{-1}\phi_i$ by the linear function $a + b \cdot (x_i'\beta/\sigma)$ and substitute it into the left-hand side of (47) to obtain

$$-\sigma \sum_0 \left[a + b \cdot (x_i'\beta/\sigma)\right] x_i + \sum_1 (y_i - x_i'\beta) x_i = 0. \quad (49)$$

Solve (49) for $\beta$ and insert it into (48) to obtain a quadratic equation in $\sigma$. If the roots are imaginary, Tobin’s method does not work. If the roots are real, one of them can be chosen arbitrarily. Once an estimate of $\sigma$ is determined, an estimate of $\beta$ can be determined linearly from (49). Amemiya (1973) showed that Tobin’s initial estimator is inconsistent. However, empirical researchers have found it to be a good starting value for iteration.

Amemiya (1973) proposed the following simple consistent estimator: We have

$$E(y_i^2 | y_i > 0) = (x_i'\beta)^2 + \sigma x_i'\beta \lambda(x_i'\alpha) + \sigma^2. \quad (50)$$

Combining (12) and (50) yields

$$E(y_i^2 | y_i > 0) = x_i'\beta E(y_i | y_i > 0) + \sigma^2, \quad (51)$$

which can be alternatively written as

$$y_i^2 = y_i x_i'\beta + \sigma^2 + \zeta_i, \quad \text{for } i \text{ such that } y_i > 0, \quad (52)$$
where \( \mathbb{E}(\xi_i | y_i > 0) = 0 \). Then, consistent estimates of \( \beta \) and \( \sigma^2 \) are obtained by applying an instrumental variables method to (52) using \((\hat{y}_i, x_i', 1)\) as the instrumental variables where \( \hat{y}_i \) is the predictor of \( y_i \) obtained by regressing positive \( y_i \) on \( x_i \) and, perhaps, powers of \( x_i \). The asymptotic distribution of the estimator is given in Amemiya (1973). A simulation study by Wales and Woodland (1980) indicates that this estimator is rather inefficient.

4.6. The EM algorithm

The EM algorithm is a general iterative method for obtaining the MLE, first proposed by Hartley (1958) and generalized by Dempster, Laird and Rubin (1977), which is especially suited for censored regression models such as Tobit models. It has good convergence properties making it especially useful for handling the more complex Tobit models, which I will discuss later, where global concavity may not hold. However, I will discuss it in the context of the Standard Tobit model because all the essential features of the algorithm can be explained for that model. I will first present the definition and the properties of the EM algorithm under a general setting and then apply it to the Standard Tobit model.

I will explain the EM algorithm in a general model where a vector of observable variables \( z \) are related to a vector of unobservable variables \( y^* \) in such a way that the value of \( y^* \) uniquely determines the value of \( z \) but not vice versa. In the Tobit model, \( \{y^*_i\} \) defined in (3) constitute the elements of \( y^* \), and \( \{y_i\} \) and \( \{w_i\} \) defined in (4) and (9) respectively constitute the elements of \( z \). Let the joint density or probability of \( y^* \) be \( f(y^*) \) and let the joint density or probability of \( z \) be \( g(z) \). Also, define \( k(y^*|z) = f(y^*)/g(z) \). We implicitly assume that \( f, g \) and \( k \) depend on a vector of parameters \( \theta \). The purpose is to maximize

\[
L(\theta) = n^{-1} \log g(z) = n^{-1} \log f(y^*) - n^{-1} \log k(y^*|z),
\]

with respect to \( \theta \). Define

\[
Q(\theta|\theta_1) = \mathbb{E}[n^{-1} \log f(y^*|\theta)|z, \theta_1],
\]

where we are taking expectation assuming \( \theta_1 \) is the true parameter value, and doing this conditional on \( z \). Then, the EM algorithm purports to maximize \( L(\theta) \) by maximizing \( Q(\theta|\theta_1) \) with respect to \( \theta \) when \( \theta_1 \) is given at each step of the iteration. The E of the name EM refers to the expectation taken in (54) and the M refers to the maximization of (54).

I will consider the convergence properties. Define

\[
H(\theta|\theta_1) = \mathbb{E}[n^{-1} \log k(y^*|z, \theta)|z, \theta_1].
\]
Then we have, from (53), (54), and (55) and the fact that \( L(\theta | \theta_1) = L(\theta) \),
\[
L(\theta) = Q(\theta | \theta_1) - H(\theta | \theta_1). \tag{56}
\]
But we have by Jensen's inequality\(^{12}\)
\[
H(\theta | \theta_1) \leq H(\theta_1 | \theta_1). \tag{57}
\]
Now, given \( \theta_1 \), let \( M(\theta_1) \) maximize \( Q(\theta | \theta_1) \) with respect to \( \theta \). Then, we have
\[
L(M) = Q(M | \theta_1) - H(M | \theta_1). \tag{58}
\]
But, since \( Q(M | \theta_1) \geq Q(\theta | \theta_1) \) by definition and \( H(M | \theta_1) \leq H(\theta_1 | \theta_1) \) by (57), we have from (56) and (58)
\[
L(M) \geq L(\theta_1). \tag{59}
\]
Thus, we have proved the desirable property that \( L \) always increases or stays constant at each step of the EM algorithm. Next, let \( \hat{\theta} \) be the MLE. Then,
\[
L(\hat{\theta}) \geq L[M(\hat{\theta})]. \tag{60}
\]
which implies that if \( L(\theta) \) has a unique maximum and if the EM algorithm converges, it converges to \( \hat{\theta} \).

We still need to prove that the EM algorithm converges to the MLE. Unfortunately, it is never easy to find reasonable and easily verifiable conditions for the convergence of any iterative algorithm. Dempster et al. (1977) do not succeed in doing this. I will merely give a sufficient set of conditions below.

The conditions I impose are (A) \( L \) is bounded and (B) the smallest characteristic root of \( -\partial^2Q(\theta | \theta_1)/\partial \theta \partial \theta' \) is bounded away from 0 for all \( \theta_1 \) and \( \theta \). Consider
\[
L(\theta_1) = Q(\theta | \theta_1) - H(\theta_1 | \theta_1), \tag{61}
\]
\(^{12}\)We have by (55)
\[
n[H(\theta | \theta_1) - H(\theta_1 | \theta_1)] = E_{\theta_1} \log \left[ k(y* | \theta) / k(y* | \theta_1) \right],
\]
where I have omitted the conditioning variable \( z \) to simplify notation and \( E_{\theta_1} \) means that the expectation is taken on the assumption that the density of \( y* \) is \( k(y* | \theta_1) \). But, by Jensen's inequality (see Rao (1973, p. 149)),
\[
E_{\theta_1} \log \left[ k(y* | \theta) / k(y* | \theta_1) \right] \leq \log E_{\theta_1} \left[ k(y* | \theta) / k(y* | \theta_1) \right].
\]
Thus, (57) follows from the above results and by noting
\[
\log E_{\theta_1} \left[ k(y* | \theta) / k(y* | \theta_1) \right] = \log k(y* | \theta) dy* = 0.
\]
and
\[ L(\theta_{r+1}) = Q(\theta_{r+1}|\theta_r) - H(\theta_{r+1}|\theta_r). \]

Since we previously established \( L(\theta_{r+1}) \geq L(\theta_r) \), assumption (A) implies
\[ \lim_{r \to \infty} [L(\theta_{r+1}) - L(\theta_r)] = 0. \]
Therefore, from (61) and (62) and using (57) and \( Q(\theta_{r+1}|\theta_r) \geq (\theta_r|\theta_r) \) by definition we have
\[ \lim_{r \to \infty} [Q(\theta_{r+1}|\theta_r) - Q(\theta_r|\theta_r)] = 0. \]

Now, denoting only the first argument of \( Q \) and suppressing its second argument, we have by a Taylor expansion of \( Q(\theta_r) \) about \( Q(\theta_{r+1}) \)
\[ Q(\theta_{r+1}) - Q(\theta_r) = \frac{1}{2} (\theta_r - \theta_{r+1})' [\frac{\partial^2 Q}{\partial \theta \partial \theta'}](\theta_r - \theta_{r+1}) \]
\[ \geq \frac{1}{2} \lambda_s \cdot (\theta_r - \theta_{r+1})'(\theta_r - \theta_{r+1}), \]
where the matrix of the second derivatives is evaluated at a point between \( \theta_r \) and \( \theta_{r+1} \) and \( \lambda_s \) denotes its smallest characteristic root. Note that in obtaining the equality above I have noted \( \partial Q(\theta_{r+1}|\theta_r)/\partial \theta_{r+1} = 0 \) by definition. Thus, (63), (64) and assumption (B) imply
\[ \lim_{r \to \infty} (\theta_{r+1} - \theta_r) = 0, \]
meaning that the EM algorithm converges.\(^{13}\)

Now, consider an application of the algorithm to the Tobit model.\(^{14}\) Define \( \theta = (\beta', \sigma^2)' \). Then, in the Tobit model we have
\[ \log f(y|\theta) = -\frac{n}{2} \log \sigma^2 - \frac{1}{2\sigma^2} \sum_{i=1}^{n} (y_i - x_i'\beta)^2, \]
and, for a given estimate \( \theta_1 = (\beta_1', \sigma_1^2)' \), the EM algorithm maximizes with respect to \( \beta \) and \( \sigma^2 \)
\[ \mathbb{E} \left[ \log f(y^*|\theta) | y, w, \theta_1 \right] \]
\[ = -\frac{n}{2} \log \sigma^2 - \frac{1}{2\sigma^2} \sum_{i=1}^{n} (y_i - x_i'\beta)^2 - \frac{1}{2\sigma^2} \sum_0 \mathbb{E} \left[ (y_i^* - x_i'\beta)^2 | w_i = 0, \theta_1 \right] \]
\[ = -\frac{n}{2} \log \sigma^2 - \frac{1}{2\sigma^2} \sum_{i=1}^{n} (y_i - x_i'\beta)^2 - \frac{1}{2\sigma^2} \sum_0 \mathbb{E} \left( y_i^* | w_i = 0, \theta_1 \right) - x_i'\beta \]
\[ - \frac{1}{2\sigma^2} \sum_0 V(y_i^* | w_i = 0, \theta_1), \]
\[ 13^{13}\text{See Wu (1983) for more discussion of the convergence of the EM algorithm.} \]
\[ 14^{14}\text{For an alternative account, see Hartley (1976c).} \]
where
\[ E(y^*_j|w_j = 0, \theta_1) = x'_j\beta_1 - \sigma_1\phi_1/(1 - \Phi_1) = y^*_j, \]
(68)
and
\[ V(y^*_j|w_j = 0, \theta_1) = \sigma_1^2 + x'_j\beta_1 \left[ \sigma_1\phi_1/(1 - \Phi_1) \right] - \left[ \sigma_1\phi_1/(1 - \Phi_1) \right]^2, \]
(69)
where \( \phi_1 = \phi(x'_j\beta_1/\sigma_1) \) and \( \Phi_1 = \Phi(x'_j\beta_1/\sigma_1) \).

From (67) it is clear that the second-round estimate of \( \beta \) in the EM algorithm, denoted \( \beta_2 \), is obtained as follows: Assume without loss of generality that the first \( n_1 \) observations of \( y_i \) are positive and call the vector of those observations \( y \) as I did in (20). Next, define an \((n - n_1)\)-vector \( y^* \) whose elements are the \( y^*_i \) defined in (68). Then, we have
\[ \beta_2 = (X'X)^{-1}X' \begin{bmatrix} y \\ y^*_0 \end{bmatrix}, \]
(70)
where \( X \) was defined after (4). In other words, the EM algorithm amounts to predicting all the unobservable values of \( y^*_i \) by their conditional expectations and treating the predicted values as if they were the observed values. The second-round estimate of \( \sigma^2 \), denoted \( \sigma_2^2 \), is given by
\[ \sigma_2^2 = n^{-1} \left[ \sum_{i=1}^{n_1} (y_i - x'_i\beta_2)^2 + \sum_{0}^{n_1} (y^*_0 - x'_i\beta_2)^2 + \sum_{0} V(y^*_i|w_i = 0, \theta_1) \right]. \]
(71)

Although this follows from the general theory of the algorithm given earlier, we can also directly show that the MLE \( \hat{\theta} \) is the equilibrium solution of the iteration defined by (70) and (71). Partition \( X = (X', X^0)' \) so that \( X \) is multiplied by \( y \) and \( X^0 \) by \( y^0 \). Then, inserting \( \hat{\theta} \) into both sides of (70) yields, after collecting terms,
\[ X'X\hat{\theta} = X'y - X^0' \left[ \delta\phi(x'_i\hat{\beta}/\sigma)/(1 - \Phi(x'_i\hat{\beta}/\sigma)) \right] \]
(72)
where the last bracket denotes an \((n - n_1)\)-dimensional vector whose typical element is given inside. But, clearly, (72) is equivalent to (47). Similarly, the MLE \( \hat{\theta} \) can be shown to be an equilibrium solution of (71).

Unfortunately, conditions (A) and (B) do not generally hold for the Tobit model. However, they do hold if the sample size is sufficiently large and if the iteration is started from a point sufficiently close to the MLE. Schmee and
Hahn (1979) performed a simulation study of the EM algorithm applied to a censored regression model (a survival model) defined by

\[ y_i^* = y_i \quad \text{if} \quad y_i^* \leq c, \]
\[ = c \quad \text{if} \quad y_i^* > c, \]

where \( y_i^* \sim N(\alpha + \beta x_i, \sigma^2) \). They generally obtained rapid convergence.

5. Properties of the Tobit MLE under non-standard assumptions

In this section I will discuss the properties of the Tobit MLE – the estimator which maximizes (42) – under various types of non-standard assumptions: heteroscedasticity, serial correlation, and non-normality. It will be shown that the Tobit MLE remains consistent under serial correlation but not under heteroscedasticity or non-normality. The same is true of the other estimators considered earlier. This result contrasts with the classical regression model in which the least squares estimator (the MLE under the normality assumption) is generally consistent under all of the three types of non-standard assumptions mentioned above.

Before proceeding with rigorous argument, I will given an intuitive explanation of the above-mentioned result. By considering (17) we see that serial correlation of \( y_i \) should not affect the consistency of the NLLS estimator, whereas heteroscedasticity changes \( \sigma \) to \( \sigma_i \) and hence invalidates the estimation of the equation by least squares. If \( y_i^* \) is not normal, eq. (17) itself is generally invalid, which leads to the inconsistency of the NLLS estimator. Though the NLLS estimator is different from the ML estimator, one can expect a certain correspondence between the consistency properties of the two estimators.

5.1. Heteroscedasticity

Hurd (1979) evaluated the probability limit of the truncated Tobit MLE when a certain type of heteroscedasticity is present in two simple truncated Tobit models: (1) the i.i.d. case (that is, the case of the regressor consisting only of a constant term) and (2) the case of a constant term plus one independent variable. Recall that the truncated Tobit model is the one in which no information is available for those observations for which \( y_i^* < 0 \) and therefore the MLE maximizes (6) rather than (5).

In the i.i.d. case, Hurd created heteroscedasticity by generating \( rn \) observations from \( N(\mu, \sigma^2) \) and \( (1 - r)n \) observations from \( N(\mu, \sigma_i^2) \). In each case, he recorded only positive observations. Let \( y_{i1}, i = 1, 2, \ldots, n_1 \), be the recorded observations. (Note \( n_1 \leq n \).) One can show that the truncated Tobit MLE of \( \mu \) and \( \sigma^2 \), denoted \( \hat{\mu} \) and \( \hat{\sigma}^2 \), are defined by equating the first two population
moments of $y_i$ to their respective sample moments,
\[
\hat{\mu} + \delta \lambda (\hat{\mu} / \hat{\sigma}) = n_1^{-1} \sum_{i=1}^{n_1} y_i,
\]
and
\[
\hat{\mu}^2 + \delta \hat{\mu} \lambda (\hat{\mu} / \hat{\sigma}) + \hat{\sigma}^2 = n_1^{-1} \sum_{i=1}^{n_1} y_i^2.
\]
Taking the probability limit of both sides of (73) and (74) and expressing \( \text{plim} n_1^{-1} \sum_{i=1}^{n_1} y_i \) and \( \text{plim} n_1^{-1} \sum_{i=1}^{n_1} y_i^2 \) as certain functions of the parameters \( \mu, \sigma^2, \sigma_2^2 \) and \( r \), one can define \( \text{plim} \hat{\mu} \) and \( \text{plim} \hat{\sigma}^2 \) implicitly as functions of these parameters. Hurd evaluated the probability limits for various values of \( \mu \) and \( \sigma_2 \) after having fixed \( r = 0.5 \) and \( \sigma_2 = 1 \). Hurd found large asymptotic biases in certain cases.

In the case of one independent variable, Hurd generated observations from \( N(\alpha + \beta x_i, \sigma_2^2) \) after having generated \( x_i \) and \( \log|\sigma_i| \) from Bivariate \( N(0,0, V_1, V_2, \rho) \). For given values of \( \alpha, \beta, V_1, V_2 \) and \( \rho \), Hurd found the values of \( \alpha, \beta \) and \( \sigma^2 \) that maximize \( E \log L \), where \( L \) is as given in (6). Those values are the probability limits of the MLE of \( \alpha, \beta \) and \( \sigma^2 \) under Hurd’s model if the expectation of \( \log L \) is taken using the same model. Again, Hurd found extremely large asymptotic biases in certain cases.

Arabmazar and Schmidt (1981) show that the asymptotic biases of the censored Tobit MLE in the i.i.d. case are not as large as those obtained by Hurd.

5.2. Serial correlation

Robinson (1982a) proved the strong consistency and the asymptotic normality of the Tobit MLE under very general assumptions about \( U_i \) (normality is presupposed) and obtained its asymptotic variance–covariance matrix, which is complicated and therefore not reproduced here. His assumptions are slightly stronger than the stationarity assumptions but are weaker than the assumption that \( U_i \) possesses a continuous spectral density. His results are especially useful since the full MLE that takes account of even a simple type of serial correlation seems computationally intractable. The autocorrelations of \( U_i \) need not be estimated in order to compute the Tobit MLE but must be estimated in order to estimate its asymptotic variance–covariance matrix. The consistent estimator proposed by Robinson (1982b) may be used for that purpose.

5.3. Non-normality

Goldberger (1980) considered an i.i.d. truncated sample model in which data are generated by a certain non-normal distribution with mean \( \mu \) and variance 1 and are recorded only when the value is smaller than a constant \( c \). Let \( y \)
represent the recorded random variable and let $\bar{y}$ be the sample mean. The researcher is to estimate $\mu$ by the MLE assuming that the data are generated by $N(\mu, 1)$. As in Hurd’s i.i.d. model, the MLE $\hat{\mu}$ is defined by equating the population mean of $y$ to its sample mean,

$$\hat{\mu} - \lambda (c - \hat{\mu}) = \bar{y}. \tag{75}$$

Taking the probability limit of both sides of (75) under the true model and putting $\text{plim} \, \hat{\mu} = \mu^*$ yields

$$\mu^* - \lambda (c - \mu^*) = \mu - h(c - \mu), \tag{76}$$

where $h(c - \mu) = E(\mu - y|y < c)$, the expectation being taken using the true model. Defining $m = \mu^* - \mu$ and $\theta = c - \mu$, we rewrite (76) as

$$m = \lambda (\theta - m) - h(\theta). \tag{77}$$

Goldberger calculated $m$ as a function of $\theta$ when the data are generated by Student’s $t$ with various degrees of freedom, Laplace and logistic distributions. The asymptotic bias was found to be especially great when the true distribution is Laplace. Goldberger also extended the analysis to the regression model with a constant term and one discrete independent variable. Arabmazar and Schmidt (1982) extended Goldber’s analysis to the case of an unknown variance and found that the asymptotic bias was further accentuated.

5.4. Tests for normality

The fact that the Tobit MLE is generally inconsistent when the true distribution is non-normal makes it important for a researcher to test whether his data are generated by a normal distribution. Nelson (1981) devised tests for normality in the i.i.d. censored sample model and the Tobit model. His tests are applications of the specification test of Hausman (1978).

In Hausman’s test, one uses the MLE $\hat{\theta}$ obtained under the null hypothesis, which is asymptotically efficient under the null hypothesis but loses consistency under an alternative hypothesis, and a consistent estimator $\hat{\theta}$, which is asymptotically less efficient than the MLE under the null hypothesis but remains consistent under an alternative hypothesis. Hausman (1978) noted that $(\hat{\theta} - \hat{\theta})' V^{-1} (\hat{\theta} - \hat{\theta})$ is asymptotically distributed under the null hypothesis as chi-square with $K$ degrees of freedom ($K$ being the number of elements in $\theta$), where $V = V(\hat{\theta}) - V(\theta)$, the difference of the asymptotic variance-covariance matrices evaluated under the null hypothesis. An advantage of Hausman’s test is that one need not know the covariance between $\hat{\theta}$ and $\hat{\theta}$ to perform the test.
Nelson's i.i.d. censored sample model is defined by

\[ y_i = y_i^* \quad \text{if} \quad y_i^* > 0, \]
\[ = 0 \quad \text{if} \quad y_i^* \leq 0, \quad i = 1, 2, \ldots, n, \]

where \( y_i^* \sim N(\mu, \sigma^2) \) under the null hypothesis. Nelson considers the estimation of \( P(y_i^* > 0) \). Its MLE is \( \Phi(\hat{\mu}/\hat{\sigma}) \) where \( \hat{\mu} \) and \( \hat{\sigma} \) are the MLE of the respective parameters. A consistent estimator is provided by \( n_1/n \) where, as before, \( n_1 \) is the number of positive observations of \( y_i \). Clearly, \( n_1/n \) is a consistent estimator of \( P(y_i^* > 0) \) under any distribution provided that it is i.i.d. Nelson derived the asymptotic variances under normality of the two estimators.

If we interpret what one is estimating by the two estimators as \( \lim_{n \to \infty} n^{-1} \sum_{i=1}^{n} P(y_i^* > 0) \), Nelson's test can be interpreted as a test of the null hypothesis against a more general misspecification than just non-normality. In fact, Nelson conducted a simulation study to evaluate the power of the test against a heteroscedastic alternative. The performance of the test was satisfactory but not especially encouraging.

In the Tobit model, Nelson considers the estimation of

\[ n^{-1}E X'y = n^{-1} \sum_{i=1}^{n} x_i \left[ \Phi(x_i'\alpha) x_i'\beta + \sigma \Phi(x_i'\alpha) \right]. \]

Its MLE is given by the right-hand side of this equation evaluated at the Tobit MLE, and its consistent estimator is provided by \( n^{-1}X'y \). Hausman's test based on these two estimators will work because this consistent estimator is consistent under general distributional assumptions on \( y \). Nelson derived the asymptotic variance-covariance matrices of the two estimators.

Nelson was ingenious in that he considered certain functions of the original parameters for which one can easily obtain estimators which are consistent under very general assumptions. However, it would be better if one could find a general consistent estimator for the original parameters themselves. An example is Powell's least absolute deviations estimator, which I discuss below.

Bera, Jarque and Lee (1982) propose using Rao's score test in testing for normality in the standard Tobit model where the error term follows the two-parameter Pearson family of distributions, which contains normal as a special case.

5.5. Non-normal Tobit

If \( u_i \) in the Tobit model (3) is not normal, one of two things can be done: (1) Specify a non-normal distribution and use the true MLE or some other estimator tailor-made for the distribution. (2) Use an estimator which is consistent under general distributions, both normal and non-normal. In this
subsection I give examples of the first approach. An example of the second approach is given in the next subsection.

Amemiya and Boskin (1974) studied the effect of wage and other independent variables on the number of months during a five-year period in which a household received welfare payments. Since the dependent variable is naturally bounded between 0 and 60, one must impose both an upper and lower truncation point if one uses a normal Tobit model. Instead, the authors assumed the dependent variable to be lognormal and hence positive, so that only an upper truncation needs to be imposed. The MLE was used.

Pokier (1978) considers the model in which the dependent variable $y$ is constrained by $a < y < b$ and its Box–Cox transformation $(y^h - 1)/\lambda$ is truncated normal.

The majority of models I will discuss in part II assume a normal distribution. Exceptions are some of the models proposed by Cragg (1971) mentioned in footnote 15 and the model of Dubin and McFadden (1980) discussed in section 11.7.

5.6. Powell's least absolute deviations estimator

Powell (1981, 1983) proposed the least absolute deviations (LAD) estimator for censored and truncated regression models, proved its consistency under general distributions, and derived its asymptotic distribution. The intuitive appeal for the LAD estimator in a censored regression model arises from the simple fact that in the i.i.d. sample case, the median (of which the LAD estimator is a generalization) is not affected by censoring (more strictly, left censoring below the mean), whereas the mean is. In a censored regression model, the LAD estimator is defined as that which minimizes $\sum_{i=1}^{n} |y_i - \text{max}(0, x_i'\beta)|$. The motivation for the LAD estimator in a truncated regression model is less obvious. Powell defines the LAD estimator in the truncated case as that which minimizes $\sum_{i=1}^{n} |\text{max}(0, x_i'\beta) - \text{max}(2^{-1}y, x_i'\beta)|$. In the censored case, the limit distribution of $\sqrt{T}(\hat{\beta} - \beta)$, where $\hat{\beta}$ is the LAD estimator, is normal with mean zero and variance–covariance matrix $4f(0)^2\lim_{T \to \infty} T^{-1}\sum_{i=1}^{T} I(x_i'\beta > 0)x_ix_i'$, where $f$ is the density of the error term and $I$ is the indicator function taking on unity if $x_i'\beta > 0$ holds and zero otherwise. In the truncated case, the limit distribution of $\sqrt{T}(\hat{\beta} - \beta)$ is normal with mean zero and variance–covariance matrix $2^{-1}A^{-1}BA^{-1}$, where

$$A = \lim_{T \to \infty} T^{-1} \sum_{i=1}^{T} I(x_i'\beta > 0)[f(0) - f(x_i'\beta)] F(x_i'\beta)^{-1} x_i x_i',$$

and

$$B = \lim_{T \to \infty} T^{-1} \sum_{i=1}^{T} I(x_i'\beta > 0)[F(x_i'\beta) - F(0)] F(x_i'\beta)^{-1} x_i x_i',$$

where $F$ is the distribution function of the error term.
Powell's estimator is attractive because it is the only known estimator which is consistent under general non-normal distributions. However, its main drawback is the computational difficulty it entails. Paarsch (1984) conducted a Monte Carlo study to compare Powell's estimator, the Tobit MLE, and Heckman's two-step estimator in the standard Tobit model with one exogenous variable under situations where the error term is distributed as normal, exponential and Cauchy. Paarsch found that when the sample size is small (50) and there is much censoring (50% of the sample), the minimum frequently occurred at the boundary of a wide region over which a grid search was performed. In large samples Powell's estimator appears to perform much better than Heckman's estimator under any of the three distributional assumptions and much better than the Tobit MLE when the errors are Cauchy.

Another problem with Powell's estimator is finding a good estimator of the asymptotic variance-covariance matrix, which does not require the knowledge of the true distribution of the error. Powell (1983) proposes a consistent estimator.

Powell observes that his proof of the consistency and asymptotic normality of the LAD estimator generally holds even if the errors are heteroscedastic. This fact makes Powell's estimator further attractive because the usual estimators are inconsistent under heteroscedastic errors as noted earlier.

6. Variations of the Standard Tobit model

In this section I discuss a few models that are variations on the Tobit model. More significant generalization of the Tobit model are discussed in part II.

Rosett (1959) proposed a model in which the observable random variables \{y_i\} are defined by

\[ y_i = \begin{cases} y_i^* & \text{if } y_i^* \leq 0, \\ 0 & \text{if } 0 < y_i^* < \alpha, \\ y_i^* - \alpha & \text{if } \alpha \leq y_i^*, \end{cases} \]

where \( y_i^* \sim N(x_i'\beta, \sigma^2) \). One can estimate \( \alpha \) as well as \( \beta \) and \( \sigma^2 \). Rosett called it a model of friction because the model implies that the dependent variable assumes a certain value (in this case 0) until a change in an independent variable overcomes the friction. At this point the dependent variable either increases or decreases depending upon the type of the stimulus. Maddala (1977) remarks that this model is useful in analyzing dividend policies, changes in wage offers by firms, and similar examples where firms respond by jumps after a certain cumulative effort.
Rosett and Nelson (1975) considered the following simple generalization of the Tobit model:

\[ y_i = \alpha_1 \quad \text{if} \quad y_i^* \leq \alpha_1, \]
\[ = y_i^* \quad \text{if} \quad \alpha_1 < y_i^* < \alpha_2, \]
\[ = \alpha_2 \quad \text{if} \quad \alpha_2 \leq y_i^*, \]

(79)

where \( y_i^* \sim N(x_i'\beta, \sigma^2) \). If \( x_i \) contains a constant term, one can assume \( \alpha_1 = 0 \) without loss of generality. Then, the Standard Tobit model is obtained as a special case by putting \( \alpha_2 = \infty \). According to Maddala (1977a), an example of a problem to which this model has been applied is the demand for health insurance by people on medicare, where both a minimum coverage and a maximum amount are imposed.

Dagenais (1969) proposed a model which is obtained by making the boundary points of Rosett’s model stochastic as follows:

\[ y_i = y_i^* \quad \text{if} \quad y_i^* \leq v_i, \]
\[ = 0 \quad \text{if} \quad v_i < y_i^* < x_{i}'\gamma + w_i, \]
\[ = y_i^* - x_{i}'\gamma \quad \text{if} \quad x_{i}'\gamma + w_i \leq y_i^*, \]

(80)

where \( y_i^* \sim N(x_i'\beta, \sigma^2) \) and \( v_i \) and \( w_i \) are also normal. Unfortunately, there is a logical inconsistency in the model because \( v_i < x_{i}'\gamma + w_i \) cannot always be guaranteed. Perhaps for this reason, this model does not seem to have been applied to real data. Dagenais (1975) begins to discuss this model but the model he actually estimated is of Type 2 Tobit, which I will discuss later.

II. Generalized Tobit Models

7. Introduction

As I stated in section 1, I will classify the majority of Tobit models into five common types according to similarities in the likelihood function. Type 1 is the Standard Tobit model which I have discussed in part I. In part II, I will define and discuss the remaining four types of Tobit models.

It is useful to characterize the likelihood function of each type of model schematically as in table 1, where each \( y_j \), \( j = 1, 2, 3 \), is assumed to be distributed as \( N(x_j'\beta, \sigma^2) \), and \( P \) denotes a probability or a density or a combination thereof. One is to take the product of each \( P \) over the observations that belong to a particular category determined by the sign of \( y_j \). Thus, in Type 1
(Standard Tobit model), \( P(y_1 < 0) \cdot P(y_1) \) is an abbreviated notation for \( \prod P(y_1^* < 0) \cdot f_{y_1}(y_1), \) where \( f_{y_1} \) is the density of \( N(x_i, \beta_{1i}, \sigma_{1i}^2) \). This expression can be rewritten as (5) after dropping the unnecessary subscript 1.

Another way to characterize the five types is by the classification of the three dependent variables which appear in table 2. In table 2 below, \( B \) is an abbreviation for Binary and \( C \) for Censored. In each type of model, the sign of \( y_1 \) determines one of the two possible categories for the observations, and a censored variable is observed in one category and unobserved in the other. Note that when \( y_1 \) is labelled \( C \), it plays two roles: the role of the variable whose sign determines categories and the role of a censored variable.

We allow for the possibility that there are constraints among the parameters of the model \( (\beta_j, \sigma_j^2) \), \( j = 1, 2, 3 \). For example, constraints will occur if the original model is specified as a simultaneous equations model in terms of \( y_1, y_2 \) and \( y_3 \). Then, the \( \beta \)'s denote the reduced-form parameters.

I will not discuss here models in which there are more than one binary variable and, hence, models whose likelihood function consists of more than two components. Such models are computationally more burdensome because they involve double or higher-order integration of joint normal densities. The only exception occurs in section 11.7, which includes models that are obvious generalizations of the Type 5 Tobit model. Neither will I discuss a simultaneous-equation Tobit model of Amemiya (1974b). The simplest two-equation case of this model is defined by \( y_{1i} = \max(y_i, y_i + x_{1i} \beta_1 + u_{1i}, 0) \) and \( y_{2i} = \max(y_{2i} + x_{2i} \beta_2 + u_{2i}, 0) \) where \( (u_{1i}, u_{2i}) \) is bivariate normal and \( y_1 y_2 < 1 \) must be assumed for the model to be logically consistent. A schematic representation of the likelihood function of this two equation model is \( P(y_{1i}, y_2) \cdot P(y_1 < 0, y_2) \cdot P(y_2 < 0, y_4) \cdot P(y_3 < 0, y_4 < 0) \) with \( y \)'s appropriately defined.

8. Type 2: $P(y_1 < 0) \cdot P(y_1 > 0, y_2)$

8.1. Definition and estimation

The Type 2 Tobit model is defined as follows:

$$y_{1i}^* = x_{1i}' \beta_1 + u_{1i}, \quad y_{2i}^* = x_{2i}' \beta_2 + u_{2i},$$

$$y_{2i} = \begin{cases} y_{2i}^* & \text{if } y_{1i}^* > 0, \\ 0 & \text{if } y_{1i}^* \leq 0, \end{cases} \quad i = 1, 2, \ldots, n,$$

(81)

where $\{u_{1i}, u_{2i}\}$ are i.i.d. drawings from a bivariate normal distribution with mean zero, variances $\sigma_1^2$ and $\sigma_2^2$, and covariance $\sigma_{12}$. It is assumed that only the sign of $y_{1i}^*$ is observed and that $y_{2i}^*$ is observed only when $y_{1i}^* > 0$. It is assumed that $x_{1i}$ are observed for all $i$ but $x_{2i}$ need not be observed for $i$ such that $y_{1i}^* \leq 0$. One may also define, as in (9),

$$w_{1i} = \begin{cases} 1 & \text{if } y_{1i}^* > 0, \\ 0 & \text{if } y_{1i}^* \leq 0. \end{cases}$$

(82)

Then, $\{w_{1i}, y_{2i}\}$ constitute the observed sample of the model. It should be noted that, unlike the Type 1 Tobit, $y_{2i}$ may take negative values.\(^{15}\) As in (4), $y_{2i} = 0$ merely signifies the event $y_{1i}^* \leq 0$.

The likelihood function of the model is given by

$$L = \prod_0 P(y_{1i}^* \leq 0) \prod_1 f(y_{2i}, y_{1i}^* > 0) P(y_{1i}^* > 0),$$

(83)

where $\prod_0$ and $\prod_1$ stand for the product over those $i$ for which $y_{2i} = 0$ and $y_{2i} \neq 0$, respectively, and $f(\cdot, y_{1i}^* > 0)$ stands for the conditional density of $y_{2i}^*$ given $y_{1i}^* > 0$. Note the similarity between (7) and (83). As in Type 1 Tobit, one can obtain a consistent estimate of $\beta_1/\sigma_1$ by maximizing the probit part of (83),

$$\text{Probit } L = \prod_0 P(y_{1i}^* \leq 0) \prod_1 P(y_{1i}^* > 0).$$

(84)

Also, (84) is a part of the likelihood function for every one of the five types of models; therefore, a consistent estimate of $\beta_1/\sigma_1$ can be obtained by the probit MLE in each of these types of model.

\(^{15}\)See Cragg (1971) for models which insure the non-negativity of $y_2$ as well as $y_1$. 
One can rewrite (83) as

\[ L = \prod_{0} P(y_i^* \leq 0) \prod_{1} \int_{0}^{\infty} f(y_i^*, y_{2i}) \, dy_i^*, \tag{85} \]

where \( f(\cdot, \cdot) \) denotes the joint density of \( y_i^* \) and \( y_{2i}^* \). One can write the joint density as the product of a conditional density and a marginal density, i.e., \( f(y_i^*, y_{2i}) = f(y_i^*|y_{2i}) f(y_{2i}) \), and determine a specific form for \( f(y_i^*|y_{2i}) \) from the well-known fact that the conditional distribution of \( y_i^* \) given \( y_{2i}^* = y_{2i} \) is normal with mean \( x_i^\prime \beta + \sigma_{12} \sigma_2^{-2}(y_{2i} - x_{2i}^\prime \beta_2) \) and variance \( \sigma_i^2 \sigma_2^{-2} \). Thus, one can further rewrite (85) as

\[ L = \prod_{0} \left[ 1 - \Phi(x_i^\prime \beta \sigma_1^{-1}) \right] \times \prod_{1} \Phi \left[ \left( x_i^\prime \beta \sigma_1^{-1} + \sigma_{12} \sigma_1^{-1} \sigma_2^{-2}(y_{2i} - x_{2i}^\prime \beta_2) \right) \right] \times \left[ 1 - \sigma_2^2 \sigma_1^{-2} \right]^{-\frac{1}{2}} \sigma_2^{-1} \phi \left[ \sigma_2^{-1}(y_{2i} - x_{2i}^\prime \beta_2) \right]. \tag{86} \]

Note that \( L \) depends on \( \sigma_1 \) only through \( \beta \sigma_1^{-1} \) and \( \sigma_{12} \sigma_1^{-1} \); therefore, if there is no constraint on the parameters, one can put \( \sigma_1 = 1 \) without any loss of generality. Then, the remaining parameters can be identified. If, however, there is at least one common element in \( \beta_1 \) and \( \beta_2 \), \( \sigma_1 \) can be also identified.

I will show how Heckman's two-step estimator can be used in this model. To obtain an equation comparable to (17), we need to evaluate \( E(y_{2i}^*|y_{2i}^* > 0) \). For this purpose we use the well-known result

\[ y_{2i}^* = x_{2i}^\prime \beta + \sigma_{12} \sigma_1^{-1} \sigma_2^{-2}(y_{1i}^* - x_{1i}^\prime \beta_1) + \xi_{2i}, \tag{87} \]

where \( \xi_{2i} \) is normally distributed independently of \( y_{1i}^* \) with mean zero and variance \( \sigma_2^2 - \sigma_{12}^2 \sigma_1^{-1} \). Using (87), one can express \( E(y_{2i}^*|y_{1i}^* > 0) \) as a simple linear function of \( E(y_{1i}^*|y_{2i}^* > 0) \), which was already obtained in part I. Using (87), one can also derive \( V(y_{2i}^*|y_{1i}^* > 0) \) easily. Thus, we obtain

\[ y_{2i} = x_{2i}^\prime \beta + \sigma_{12} \sigma_1^{-1} \lambda \left( x_{1i}^\prime \alpha_1 \right) + \epsilon_{2i}, \quad \text{for } i \text{ such that } y_{2i} > 0, \tag{88} \]

where \( \alpha_1 = \beta_1 \sigma_1^{-1}, E\epsilon_{2i} = 0, \) and

\[ V\epsilon_{2i} = \sigma_2^2 - \sigma_{12}^2 \sigma_1^{-2} \left[ x_{1i}^\prime \alpha_1 \lambda \left( x_{1i}^\prime \alpha_1 \right) + \lambda \left( x_{1i}^\prime \alpha_1 \right)^2 \right]. \tag{89} \]

As in the case of the Type 1 Tobit, Heckman's two-step estimator is the LS estimator applied to (88) after replacing \( \alpha_1 \) with the probit MLE. The asymp-
T. Amemiya, Tobit models: A survey

T. Amemiya, Tobit models: A survey 33

The asymptotic distribution of the estimator can be similarly obtained as in section 4.3 by defining \( \eta_t \) in the same way as before. It was first derived by Heckman (1979).

The Standard Tobit (Type 1) is a special case of Type 2, in which \( y_t^* - y_2^* \). Therefore, (88) and (89) will be reduced to (17) and (18) by putting \( x_{1t}' \beta_1 = x_{2t}' \beta_2 \) and \( \sigma_1^2 = \sigma_2^2 = \sigma_{12} \).

A generalization of the two-step method applied to (29) can be easily defined for this model but will not be discussed.

It is important to note, as pointed out by Olsen (1980), that the consistency of Heckman's estimator does not require the joint normality of \( y_t^* \) and \( y_2^* \) provided that \( y_t^* \) is normal and eq. (87) holds with \( \xi_2 \) independently distributed of \( y_t^* \) but not necessarily normal. For, then, (88) would be still valid. As pointed out by Lee (1982), the asymptotic variance-covariance matrix of Heckman's estimator can be consistently estimated under these less restrictive assumptions by using White's estimator analogous to the one mentioned after eq. (28). Note that White's estimator does not require (89) to be valid.

8.2. A special case of independence

Dudley and Montmarquette (1976) analyzed whether or not the United States gives foreign aid to a particular country and, if it does, how much foreign aid it gives using a special case of the model (81) where the independence of \( u_{1i} \) and \( u_{2i} \), is assumed. In their model, the sign of \( y_1^* \), determines whether aid is given to the \( i \)th country, and \( y_2^* \) determines the actual amount of aid. They used the probit MLE to estimate \( \beta_1 \) (assuming \( \sigma_1 = 1 \)) and the least squares regression of \( y_{2i} \) on \( x_{2i} \) to estimate \( \beta_2 \). The LS estimator of \( \beta_2 \) is consistent in their model because of the assumed independence between \( u_{1i} \) and \( u_{2i} \). This makes their model computationally advantageous. However, it seems unrealistic to assume that the potential amount of aid, \( y_2^* \), is independent of the variable which determines whether or not aid is given, \( y_1^* \). This model is the opposite extreme of the Tobit model, which can be regarded as a special case of Type 2 model where there is total dependence between \( y_1^* \) and \( y_2^* \) in the whole spectrum of models (with varying correlation between \( y_1^* \) and \( y_2^* \)) contained in Type 2.

Because of the computational advantage mentioned above, this ‘independence’ model and its variations were frequently used in econometric applications in the 1960's and early 70's. In many of these studies, authors made the additional linear probability assumption: \( P(y_{1i}^* > 0) = x_{1i}' \beta_1 \), which enabled them to estimate \( \beta_1 \) (as well as \( \beta_2 \)) consistently by the least squares method. For examples of these studies, see Huang (1964) and Wu (1965).

8.3. Gronau (1973)

I take up Gronau's model as the first example of the Type 2 Tobit model because he seems to be the first person to suggest an empirical model of this
type, even though he did not use all the information provided by the model and sometimes used incorrect estimation procedures, as I will show below. His model of labor supply, based on the idea of a reservation wage, has since been used and extended by many authors.

First, I will briefly sketch Gronau's theory of how a housewife decides whether or not to work and how much to work. Gronau assumes that the offered wage $W^0$ is given to each housewife independently of hours worked $H$, rather than as a schedule $W^0 (H)$. Given $W^0$, a housewife maximizes her utility function $U(C, X)$ subject to $X = W^0 H + V$ and $C + H = T$, where $C$ is time spent at home for child care, $X$ represents all other goods, $T$ is total available time, and $V$ is other income. Thus, a housewife does not work if

\[ \frac{(\partial U/\partial C)/(\partial U/\partial X)}{H} > W^0, \]

and works if the inequality in (90) is reversed. If she works, the hours of work $H$ and the actual wage rate $W$ must be such that

\[ \frac{(\partial U/\partial C)/(\partial U/\partial X)}{H} = W. \]

Gronau calls the left-hand side of (90) the housewife's value of time, or, more commonly, the reservation wage, denoted $W'$.\(^{16}\)

Assuming that both $W^0$ and $W'$ can be written as linear combinations of independent variables plus error terms, his model may be statistically described as follows:

\[ W_i^0 = x_i \beta_2 + u_{2i}, \quad W_i' = z_i \alpha + v_i, \]

\[ W_i = \begin{cases} W_i^0 & \text{if } W_i^0 > W_i', \\ 0 & \text{if } W_i^0 \leq W_i', \end{cases} \quad i = 1, 2, \ldots, n, \]

where $(u_{2i}, v_i)$ is an i.i.d. drawing from a bivariate normal distribution with mean zero, variances $\sigma_u^2$ and $\sigma_v^2$, and covariance $\sigma_{uv}$. Thus, the model can be written in the form of (81) by putting $W_i^0 - W_i' = y_i^*$ and $W_i^0 = y_i^*$. Note that $H$ (hours worked) is not explained by this statistical model though it is determined by Gronau's theoretical model. A statistical model explaining $H$ as well as $W$ was later developed by Heckman (1974). I will discuss this in the section on Type 3 models.

Since the model (91) can be transformed into the form (81) in such a way that the parameters of (91) can be determined from the parameters of (81), all

\(^{16}\)For a more elaborate derivation of the reservation wage model based on search theory, see Gronau (1974).
the parameters of the model are identifiable except $V(W_i^0 - W_i^r)$, which can be set equal to 1 without loss of generality. If, however, at least one element of $x_{2i}$ is not included in $z_i$, all the parameters are identifiable. They can be estimated by the MLE or Heckman’s two-step estimator by procedures described in section 8.1 above. One can also use the probit MLE (the first step of Heckman’s two-step) to estimate a certain subset of the parameters. However, the main estimation method used by Gronau is not among the above. I will describe his method after correcting a minor error.

The full likelihood function of Gronau’s model (91) can be written as

$$L = \prod_0 P(W_i^0 \leq W_i^r) \prod_1^{W_i} f(W_i^r, W_i^r) dW_i^r,$$  \hspace{1cm} (92)

where $\prod_0$ and $\prod_1$ are the products over those observations for which $W_i^0 \leq W_i^r$ and $W_i^0 > W_i^r$, respectively, and $f(\cdot, \cdot)$ is the joint density of $W_i^0$ and $W_i^r$. Gronau assumes that $u_2$ and $v_i$ are independent. Under this assumption, (92) can be written as

$$L = L^* \prod_1 \sigma_u^{-1} \phi \left[ \alpha, \beta, \sigma_\alpha \right] \left[ W_i - x_{2i}, \beta_2 \right],$$  \hspace{1cm} (93)

where

$$L^* = \prod_0 \left[ 1 - \Phi \left( \left( \sigma_u^2 + \sigma_v^2 \right)^{-\frac{1}{2}} \left( x_{2i} \beta_2 - z_i \alpha \right) \right) \right]$$

$$\times \prod_1 \Phi \left[ \sigma_\alpha^{-1} \left( W_i - z_i \alpha \right) \right].$$  \hspace{1cm} (94)

Maximizing (93) yields the MLE of $\alpha, \beta_2, \sigma_u$ and $\sigma_\alpha$, which are consistent and asymptotically efficient under Gronau’s independence assumption. Maximizing (94) yields estimates of $\alpha, \beta_2$ and $\sigma_v$ which are consistent but asymptotically not fully efficient.

Gronau’s method consists of two steps. The first step is carried out as follows: We have under Gronau’s independence assumption

$$E(W_i|W_i^r < W_i^0) = x_{2i} \beta_2 + \left( \sigma_u^2 + \sigma_v^2 \right)^{-\frac{1}{2}} \alpha \sigma_u^2 \Phi^{-1} \phi,$$  \hspace{1cm} (95)

Gronau specifies that the independent variables in the $W^r$ equation include woman’s age and education, family income, number of children, and husband’s age and education, whereas the independent variables in the $W^0$ equation include only woman’s age and education. However, Gronau readily admits to the arbitrariness of the specification and the possibility that all the variables are included in both.

This may not be a realistic assumption since common independent variables, which are excluded from the set of regressors, may be included in both $u_2$ and $v_i$. The assumption is not necessary if one uses either the MLE or Heckman’s two-step estimator. It should be noted that the independence of $u_2$ and $v_i$ does not imply the independence of $u_2$ and $u_2$, in (81), so that Gronau’s model is not as simple as the model considered in section 8.2 above. Also note that this assumption makes all the parameters identifiable even if no element of $a$ is set equal to zero.
where $\phi_i$ and $\Phi_i$ are $\phi$ and $\Phi$ evaluated at $(\sigma^2 + \sigma_i^2)^{-\frac{1}{2}}(x_{2i}^2, \beta_2 - z_i')$. Since Gronau's data are such that there are many individuals with the same value of the independent variables, one can estimate $\Phi_i$ directly by the ratio of the number of working wives to the number of wives with the characteristics $x_i$. Given this estimate, denoted $\hat{\phi}_i$, one can estimate $\phi_i$ by $\hat{\phi}_i = \phi [ \Phi_i^{-1}(\hat{\Phi}_i) ]$. Next, one regresses positive $W_i$ on $x_{2i}$ and $\hat{\Phi}_i^{-1}\hat{\phi}_i$ to estimate $\beta_2$. This estimate, denoted $\hat{\beta}_2$, is consistent (provided that the above estimates of $\phi_i$ and $\Phi_i$ are consistent), and, therefore, the first problem of the first estimation method is solved. In the second step, Gronau maximizes $L^*$ after replacing $\beta_2$ by $\hat{\beta}_2$.

Despite the minor error in the estimation method, Gronau's article made a significant econometric contribution (besides a substantive empirical contribution which I have ignored) by suggesting a two-step method based on the conditional expectation equation, which became a precursor of Heckman's two-step estimator.

8.4. Other applications

Nelson (1977) noted that a Type 2 Tobit model arises if $y_0$ in (1) is assumed to be a random variable with its mean equal to a linear combination of independent variables. He reestimated Gronau's model by maximizing the correct likelihood function (93).

Dagenais (1975) used a Type 2 Tobit model to analyze household purchase of automobiles. In this model, $y_2^*$ in (81) represents the desired expenditure on a car and $x_2$ includes permanent income, education, and the number of children. He assumes that a household purchases a car if $y_2^*$ exceeds a stochastic threshold $S = \theta_1 + \theta_2A + v$, where $A$ is the dummy variable taking unity if the household anticipated buying a car at the time of a prior questionnaire and the actual value of purchase $y_2 = y_2^*$ if $y_2^* > S$. Thus, $y_2^* - S$ plays the role of $y_1^*$ in (81). Like Gronou, Dagenais assumes independence between $y_2^*$ and $S$, and, in addition, he assumes equality of the variances of $y_2^*$ and $S$. These assumptions are not necessary for identification. Dagenais' model, like Gronou's, has a weakness in that an arbitrary separation of the independent variables into some which go into the $y_1^*$ equation and some which go into the $S$ equation ($W^*$ equation and $W^*$ equation in Gronou's model) is maintained.

In the study of Westin and Gillen (1978), $y_2^*$ represents the parking cost with $x_2$ including zonal dummies, wage rate (as a proxy for value of walking time), and the square of wage rate. A researcher observes $y_2^* = y_2$ if $y_2^* < C$ where $C$ represents transit cost, which itself is a function of independent variables plus an error term.

\footnote{Gronau actually omitted $\sigma_i^2$ from the expression for $L^*$, which renders his estimates inconsistent.}
9. Type 3: \( P(y_1 < 0) \cdot P(y_1, y_2) \)

9.1. Definition and estimation

The Type 3 Tobit model is defined as follows:

\[
y_{1t}^* = x_{1t}' \beta_1 + \epsilon_{1t},
\]

\[
y_{2t}^* = x_{2t}' \beta_2 + \epsilon_{2t},
\]

\[
y_{1t} = \begin{cases} y_{1t}^* & \text{if } y_{1t}^* > 0, \\ 0 & \text{if } y_{1t}^* \leq 0, \end{cases}
\]

\[
y_{2t} = \begin{cases} y_{2t}^* & \text{if } y_{2t}^* > 0, \\ 0 & \text{if } y_{2t}^* \leq 0, \end{cases}
\]

where \( \{ \epsilon_{1t}, \epsilon_{2t} \} \) are i.i.d. drawings from a bivariate normal distribution with mean zero, variances \( \sigma_1^2 \) and \( \sigma_2^2 \), and covariance \( \sigma_{12} \). Note that this model differs from Type 2 only in that \( y_{1t}^* \) is also observed when it is positive in this model.

Since the estimation of this model can be handled similarly to that of Type 2, I will discuss it only briefly. Instead, in the following I will give a detailed discussion of the estimation of Heckman's model (1974), which constitutes the structural-equations version of the model (96).

The likelihood function of the model (96) can be written as

\[
L = \prod_{t=1}^{n} P(y_{1t}^* \leq 0) \prod_{t=1}^{n} f(y_{1t}, y_{2t}),
\]

where \( f(\cdot, \cdot) \) is the joint density of \( y_{1t}^* \) and \( y_{2t}^* \). Since \( y_{1t}^* \) is observed when it is positive, all the parameters of the model are identifiable, including \( \sigma_1^2 \).

Heckman's two-step estimator was originally proposed by Heckman (1976a) for this model. Here we obtain two conditional-expectation equations, eqs. (17) and (88), for \( y_1 \) and \( y_2 \), respectively. [Add subscript 1 to all the variables and the parameters in (17) to conform to the notation of the present section.] In the first step of the method, \( \alpha_1 = \hat{\beta}_1 \sigma_1^{-1} \) is estimated by the probit MLE \( \hat{\alpha}_1 \). In the second step, least squares is applied separately to (17) and (88) after replacing \( \alpha_1 \) by \( \hat{\alpha}_1 \). The asymptotic variance-covariance matrix of the resulting estimates of \( (\beta_1, \sigma_1) \) is given in (28) and that for \( (\beta_2, \sigma_{12} \sigma_1^{-1}) \) can be similarly obtained. The latter is given by Heckman (1979). A consistent estimate of \( \sigma_2 \) can be obtained using the residuals of eq. (88). As Heckman (1976a) suggested and as I noted in section 4.3, a more efficient WLS can be used for each equation in
the second-step of the method. An even more efficient GLS can be applied simultaneously to the two equations. However, even GLS is not fully efficient compared to MLE, and the added computational burden may not be sufficiently compensated for by the gain in efficiency. A two-step method based on unconditional means of $y_1$ and $y_2$, which is a generalization of the method discussed in section 3.3, can be also used for this model.

Wales and Woodland (1980) compared the LS estimator, Heckman's two-step estimator, probit MLE, conditional MLE (using only those who worked), MLE, and another inconsistent estimator in a Type 3 Tobit model in a simulation study with one replication (sample size 1000 and 5000). The particular model they used is the labor supply model of Heckman (1974), which I will discuss in the next subsection.

Heckman's model differs from Gronau's model (91) in that Heckman includes the determination of hours worked $H$ in his model. Like Gronau, Heckman assumes that the offered wage $W^0$ is given independently of $H$; therefore, Heckman's $W^0$ equation is the same as Gronau's:

$$W_i^0 = x_i'\beta_2 + u_{2i}.$$  \hfill (98)

Heckman defines $W' = (\partial U/\partial C)/(\partial U/\partial X)$ and specifies

$$W'_i = \gamma H_i + z_i'\alpha + v_i.$$ \hfill (99)

It is assumed that the $i$th individual works if

$$W'_i(H_i = 0) \equiv z_i'\alpha + v_i < W^0_i,$$ \hfill (100)

and then, the wage $W_i'$ and hours worked $H_i$ are determined by solving (98) and (99) simultaneously after putting $W_i^0 = W'_i = W_i$. Thus, we can define

\footnote{Though Heckman's model (1974) is a simultaneous-equations model, Heckman's two-step estimator studied by Wales and Woodland is essentially a reduced-form estimator which I have discussed in the present section, rather than the structural equation version I will discuss in the next subsection.}

\footnote{For a panel-data generalization of Heckman's model, see Heckman and MaCurdy (1980).}

\footnote{Actually, Heckman uses $\log W'$ and $\log W^0$. The independent variables $x_i$ include husband's wage, asset income, prices, and individual characteristics, and the $z$ include housewife's schooling and experience.}
Heckman's model as

\[ W_i - x_{i1}^* \beta_1 + u_{2i}, \quad (101) \]

and

\[ W_i = \gamma H_i + z_i^* \alpha + v_i, \quad (102) \]

for those \( i \) for which desired hours of work

\[ H_i^* = x_{i1}^* \beta_1 + u_{1i} > 0, \quad (103) \]

where \( x_{i1}^* \beta_1 = \gamma^{-1}(x_{i1} \beta_2 - z_i^* \alpha) \) and \( u_{1i} = \gamma^{-1}(u_{2i} - v_i) \). Note that (100) and (103) are equivalent because \( \gamma > 0 \).

I will call (101) and (102) the structural equations; then, (101) and the identity part of (103) constitute the reduced form equations. The reduced form equations of Heckman's model can be shown to correspond to the Type 3 Tobit model (96) if we put \( H^* = y_1^* \), \( H = y_1 \), \( W^0 = y_2^* \), and \( W = y_2 \). Since I have already discussed the estimation of the reduced-form parameters in the context of the model (96), I will now discuss the estimation of the structural parameters.

Heckman (1974) estimated the structural parameters by MLE. In the next two subsections I will discuss three alternative methods of estimating the structural parameters.

### 9.3. Heckman (1976a)

This article proposes the Heckman two-step estimator of the reduced-form parameters, which I have discussed in section 9.1 above, but also reestimates the labor supply model of Heckman (1974) using the structural equation version. Since (101) is a reduced-form as well as a structural equation, the estimation of \( \beta_2 \) is done in the same way as I have discussed in section 9.1: namely, by applying least squares to the regression equation for \( E(W_i | H_i^* > 0) \) after estimating the argument of \( \lambda \) (the hazard rate) by probit MLE. So I will only discuss the estimation of (102) here. Rewrite (102) as

\[ H_i = \gamma^{-1} W_i - z_i^* \alpha \gamma^{-1} - \gamma^{-1} v_i. \quad (104) \]

By subtracting \( E(v_i | H_i^* > 0) \) from \( v_i \) and adding the same, we rewrite (104) further as

\[ H_i = \gamma^{-1} W_i - z_i^* \alpha \gamma^{-1} - \sigma_{1v} \sigma_1^{-1} \gamma^{-1} \lambda \left( x_{i1} \beta_1 / \sigma_1 \right) - \gamma^{-1} \epsilon_i, \quad (105) \]

where \( \sigma_{1v} = \text{cov}(u_{1i}, v_i) \), \( \sigma_1^2 = V u_{1i} \) and \( \epsilon_i = v_i - E(v_i | H_i^* > 0) \). Then, consistent
estimates of $\gamma^{-1}$, $\alpha \gamma^{-1}$ and $\sigma_1 \sigma_1^{-1} \gamma^{-1}$ are obtained by the least squares regression applied to (105) after replacing $\beta_1/\sigma_1$ by its probit MLE and $W_i$ by $\hat{W}_i$, the least squares predictor of $W_i$ obtained by applying Heckman's two-step estimator to (101). The asymptotic variance–covariance matrix of this estimator can be deduced from the results in Heckman (1978), who considered the estimation of a more general model (which I will discuss in the section on Type 5 Tobit models).

Actually, there is no apparent reason why one must first solve (102) for $H_i$ and proceed as I have indicated above. Heckman could just as easily have subtracted and added $E(v_iH_i^*>0)$ to (102) itself and proceeded similarly. This method would yield alternative consistent estimates. Inferring from a well-known fact that the two-stage least squares estimates of the standard simultaneous equations model yield asymptotically equivalent estimates regardless of which normalization is chosen, I conjecture that the Heckman two-step method applied to (102) and (104) would also yield asymptotically equivalent estimates of $\gamma$ and $\alpha$.

Lee, Maddala and Trost (1980) extended Heckman's simultaneous-equations two-step estimator and its WLS version (taking account of the heteroscedasticity) to more general simultaneous-equations Tobit models and obtained their asymptotic variance–covariance matrices.

9.4. Amemiya's LS and GLS

Amemiya (1978 and 1979) proposed a general method of obtaining the estimates of the structural parameters from given reduced-form parameter estimates in general Tobit-type models and derived the asymptotic distribution. Suppose that a structural equation and the corresponding reduced-form equations are given by

\[ y = Y\gamma + X_1\beta + u, \quad [y, Y] = X[\pi, \Pi] + V, \]  

where $X_1$ is a subset of $X$. Then the structural parameters $\gamma$ and $\beta$ are related to the reduced-form parameters $\pi$ and $\Pi$ in the following way:

\[ \pi = \Pi\gamma + J\beta, \]  

where $J$ is a known matrix consisting of only ones and zeros. It is assumed that $\pi$, $\gamma$ and $\beta$ are vectors and $\Pi$ and $J$ are matrices of conformable sizes. Eq. (107) holds for Heckman's model and more general simultaneous-equations Tobit models, as well as the standard simultaneous-equations model.

Now, suppose certain estimates $\hat{\pi}$ and $\hat{\Pi}$ of the reduced-form parameters are given. Then, using them, we rewrite (107) as

\[ \hat{\pi} = \hat{\Pi}\gamma + J\beta + (\hat{\pi} - \pi) - (\hat{\Pi} - \Pi)\gamma. \]
Amemiya proposed applying LS and GLS estimation to (108). From Amemiya’s (1978) result, one can infer that Amemiya’s GLS applied to Heckman’s model yields more efficient estimates than Heckman’s simultaneous-equations two-step estimator discussed above. Amemiya (1982) shows the superiority of the Amemiya GLS estimator to the WLS version of the Lee–Maddala–Trost estimator in a general simultaneous-equations Tobit model.

9.5. Other examples

Shishko and Rostker (1976) used Heckman’s model to explain the wage and hours worked in a second job. They estimated the wage equation (101) by least squares (yielding inconsistent estimates) and estimated the hours equation (104) by the Tobit MLE after replacing \( W_i \) by its least squares predictor. There is little justification for the second procedure even if the first yielded consistent estimates.

Roberts, Maddala and Enholm (1978) estimated two types of simultaneous-equations Tobit models to explain how utility rates are determined. One of their models has a reduced form which is essentially Type 3 Tobit and the other is a simple extension of Type 3.

The structural equations of their first model are

\[
y^*_{2i} = x^*_2 \beta_2 + u_{2i},
\]

and

\[
y^*_{3i} = y^*_{2i} x^*_3 \beta_3 + u_{3i},
\]

where \( y^*_{2i} \) is the rate requested by the \( i \)th utility firm, \( y^*_{3i} \) is the rate granted for the \( i \)th firm, \( x^*_2 \) includes the embedded cost of capital and the last rate granted minus the current rate being earned, and \( x^*_3 \) includes only the last variable mentioned. It is assumed that \( y^*_{2i} \) and \( y^*_{3i} \) are observed only if

\[
y^*_{3i} \equiv z_i \alpha + v_i > 0,
\]

where \( z_i \) include the earnings characteristics of the \( i \)th firm. (\( V_i \) is assumed to be unity.) The variable \( y^*_{2i} \) may be regarded as an index affecting a firm’s decision as to whether or not it requests a rate increase. The above model can be labelled as \( P(y_1 < 0) \cdot P(y_1 > 0, y_2, y_3) \) in my short-hand notation and therefore is a simple generalization of Type 3. The author’s estimation method is that of Lee, Maddala and Trost (1978) and can be described as follows: (1) Estimate \( \alpha \) by the probit MLE. (2) Estimate \( \beta_2 \) by Heckman’s two-step method. (3) Replace \( y^*_{2i} \) in the right-hand side of (110) by \( \hat{y}^*_2 \) obtained in step (2) and estimate \( \gamma \) and \( \beta_3 \) by the least squares applied to (110) after adding the hazard rate term \( E(u_{3i} | y^*_{3i} > 0) \).
The second model of Roberts et al. is the same as the first model except that (111) is replaced by

\[ y_{2i}^* > R_i, \]  

(112)

where \( R_i \) refers to the current rate being earned, an independent variable. Thus, this model is essentially Type 3. (It would be exactly Type 3 if \( R_i = 0 \).) The estimation method is as follows: (1) Estimate \( \beta_2 \) by the Tobit MLE. (2) Repeat (3) as described in the preceding paragraph.

Nakamura, Nakamura and Cullen (1979) estimated essentially the same model as Heckman (1974) using Canadian data on married women. They used the WLS version of Heckman's simultaneous-equations two-step estimator; that is, they applied WLS to (105). Nakamura and Nakamura (1981) estimated a more elaborate version of the preceding model incorporating income tax, leading to a complex nonlinear hours equation.

Hausman and Wise (1976, 1977, 1979) used Type 3 and its generalizations to analyze the labor supply of participants in the Negative Income Tax (NIT) experiments. Their models are truncated models since they used observations on only those who participated in the experiments. The first model of Hausman and Wise (1977) is a minor variation of the Standard Tobit model where earnings \( Y \) follow

\[ Y_i = Y_i^* \text{ if } Y_i^* < L_i, \quad Y_i^* \sim \mathcal{N}(x_i' \beta, \sigma^2), \]  

(113)

where \( L_i \) is a (known) poverty level which qualifies the \( i \)th person to participate in the NIT program. It varies systematically with family size. The model is estimated by LS and MLE. (The LS estimates were always found to be smaller in absolute value, confirming Greene's result given in section 4.2.) In the second model of the same article, earnings are split into wage and hours as \( Y = W \cdot H \), leading to the same equations as Heckman's (101) and (102) except that the conditioning event is

\[ \log W_i + \log H_i < \log L_i, \]  

(114)

instead of Heckman's (113). Thus, this model is a simple extension of Type 3 and belongs to the same type of models as the first model of Roberts, Maddala and Enholm (1978), which I discussed earlier, except for the fact that the model of Hausman and Wise is a truncated one. The model of Hausman and Wise (1979) also belongs to this type. The model of their (1976) article is an extension of (113), where earnings observations are split into the pre-experiment (subscript 1) and experiment (subscript 2) periods as

\[ Y_{1i} = Y_{1i}^* \quad \text{and} \quad Y_{2i} = Y_{2i}^* \text{ if } Y_{1i}^* < L_i. \]  

(115)
Thus, the model is essentially Type 3, except for a minor variation due to the fact that $L_i$ varies with $i$.

10. Type 4: $P(y_1 < 0, y_3) \cdot P(y_1, y_2)$

10.1. Definition and estimation

The Type 4 Tobit model is defined as follows:

$$y_{3i}^* = x_{1i}' \beta_1 + u_{1i},$$

$$y_{2i}^* = x_{2i}' \beta_2 + u_{2i},$$

$$y_{3i}^* = x_{3i}' \beta_3 + u_{3i},$$

$$y_{1i} = y_{1i}^* \text{ if } y_{1i}^* > 0,$$

$$= 0 \text{ if } y_{1i}^* \leq 0,$$

$$y_{2i} = y_{2i}^* \text{ if } y_{2i}^* > 0,$$

$$= 0 \text{ if } y_{2i}^* \leq 0,$$

$$y_{3i} = y_{3i}^* \text{ if } y_{3i}^* \leq 0,$$

$$= 0 \text{ if } y_{3i}^* > 0, \quad i = 1, 2, \ldots, n,$$

(116)

where $\{u_{1i}, u_{2i}, u_{3i}\}$ are i.i.d. drawings from a trivariate normal distribution.

This model differs from Type 3 defined by (96) only by the addition of $y_{3i}^*$, which is observed only if $y_{1i}^* \leq 0$. The estimation of this model is not significantly different from that of Type 3. The likelihood function can be written as

$$L = \prod_{i=1}^{n} \int_{-\infty}^{0} f_3(y_{1i}^*, y_{3i}) \, dy_{1i}^* \cdot f_2(y_{1i}, y_{2i}),$$

(117)

where $f_3(\cdot, \cdot)$ is the joint density of $y_{1i}^*$ and $y_{3i}^*$ and $f_2(\cdot, \cdot)$ is the joint density of $y_{1i}^*$ and $y_{2i}^*$. Heckman's two-step method for this model is similar to the method for the preceding model. However, one must deal with three conditional expectation equations in the present model. The equation for $y_{3i}$ will be slightly different from the other two because the variable is non-zero when $y_{1i}^*$ is non-positive. We obtain

$$E(y_{3i} | y_{1i}^* \leq 0) = x_{3i}' \beta_3 - \sigma_3 \sigma_1^{-1} \lambda(-x_{1i}' \beta_1 / \sigma_1).$$

(118)
I will discuss three examples of the Type 4 Tobit model below: Kenny, Lee, Maddala and Trost (1979), Nelson and Olson (1978), and Tomes (1981). In the first two models, the $y^*$ equations are written as simultaneous equations, like Heckman's model (1974), for which the reduced-form equations take the form of (116). Tomes' model has a slight twist. The estimation of the structural parameters of such models can be handled in much the same way as the estimation of Heckman's model (1974): that is, by either Heckman's simultaneous-equations two-step method (and its Lee-Maddala-Trost extension) or by Amemiya's LS and GLS, both of which I discussed in section 9 above.

In fact, these two estimation methods can easily accommodate the following very general simultaneous-equations Tobit model:

$$\Gamma' y_i^* = B' x_i + u_i, \quad i = 1, 2, \ldots, n,$$

where the elements of the vector $y_i^*$ contain the following three types of variables: (1) always completely observable, (2) sometimes completely observable and sometimes observed to lie in intervals, and (3) always observed to lie in intervals. Note that the variable classified as C in table 2 belongs to class (2) above, and the variable classified as B belongs to class (3). The models of Heckman (1974), Kenny, Lee, Maddala and Trost (1979), and Nelson and Olson (1978), as well as a few more models I will discuss under Type 5 such as Heckman (1978), are all special cases of the model (119).

10.2. Kenney, Lee, Maddala and Trost (1979)

These authors tried to explain earnings differentials between those who went to college and those who did not. I will explain their model using the variables appearing in (116). In their model, $y_1^*$ refers to the desired years of college education, $y_2^*$ the earnings of those who go to college, and $y_3^*$ the earnings of those who do not go to college. A small degree of simultaneity is introduced into the model by letting $y_2^*$ appear in the right-hand side of the $y_2^*$ equation. The authors used the MLE. They note that the MLE iterations did not converge when started from the LS estimates, but did converge very fast when started from Heckman's two-step estimates (simultaneous-equations version).

10.3. Nelson and Olson (1978)

The empirical model actually estimated by these authors is more general than Type 4 and is a general simultaneous-equations Tobit model (119). The Nelson–Olson empirical model involves the following four elements of the
vector \( y^* \):

\[ y_1^* = \text{time spent on vocational school training, completely observed if } y_1^* > 0, \]
\[ \quad \text{and otherwise observed to lie in the interval } (-\infty, 0], \]
\[ y_2^* = \text{time spent on college education, observed to lie in one of the three intervals } (-\infty, 0], (0, 1] \text{ and } (1, \infty), \]
\[ y_3^* = \text{wage, always completely observed,} \]
\[ y_4^* = \text{hours worked, always completely observed.} \]

These variables are related to each other by simultaneous equations. However, they merely estimate each reduced-form equation separately by various appropriate methods and obtain the estimates of the structural parameters from the estimates of the reduced-form parameters in an arbitrary way.

The model which Nelson and Olson analyze theoretically in more detail is the following two-equation model:

\[ y_{1i}^* = \gamma_1 y_{2i} + x_{1i}' \alpha_1 + v_{1i}, \]
\[ \text{and} \]
\[ y_{2i} = \gamma_2 y_{1i}^* + x_{2i}' \alpha_2 + v_{2i}, \]

where \( y_{2i} \) is always observed and \( y_{1i}^* \) is observed to be \( y_{1i}^* > 0 \). This model may be used, for example, if one is interested in explaining only \( y_1^* \) and \( y_2^* \) in the Nelson–Olson empirical model. The likelihood function of this model may be characterized by \( P(y_1 < 0, y_2) \cdot P(y_1, y_2) \), and therefore, the model is a special case of Type 4.

Nelson and Olson proposed estimating the structural parameters of this model by the following sequential method: (1) Estimate the parameters of the reduced-form equation for \( y_1^* \) by the Tobit MLE and that for \( y_2^* \) by LS. (2) Replace \( y_{2i} \) in the right-hand side of (120) by its LS predictor obtained in step (1) above and estimate the parameters of (120) by the Tobit MLE. (3) Replace \( y_{1i}^* \) in the right-hand side of (121) by its predictor obtained in step (1) and estimate the parameters of (121) by LS. Amemiya (1979) obtained the asymptotic variance–covariance matrix of the Nelson–Olson estimator and showed that the Amemiya GLS (see section 9.4) based on the same reduced-form estimates is asymptotically more efficient.

10.4. Tomes (1981)

This article studies a simultaneous relationship between the inheritance and the recipient’s income. Though it is not stated explicitly, Tomes’ model can be
defined by

\[ y_{1t}^* = y_{1t} y_{2t} + x_{1t}' \beta_1 + u_{1t}, \quad (122) \]

\[ y_{2t} = y_{2t} y_{1t} + x_{2t}' \beta_2 + u_{2t}, \quad (123) \]

\[ y_{yt} = y_{yt}^* \quad \text{if} \quad y_{yt}^* > 0, \]

\[ = 0 \quad \text{if} \quad y_{yt}^* \leq 0, \quad (124) \]

where \( y_{yt}^* \) is the potential inheritance, \( y_{yt} \) is the actual inheritance, and \( y_{2t} \) is the recipient's income. Note that this model differs from Nelson's model defined by (120) and (121) only in that \( y_{yt} \), not \( y_{yt}^* \), appears in the right-hand side of (123). Assuming \( \gamma_1 \gamma_2 < 1 \) for the logical consistency of the model [as in Amemiya (1974) and mentioned in section 7], we may rewrite (122) as

\[ y_{yt}^* = (1 - \gamma_1 \gamma_2)^{-1} \left[ (1 - \gamma_1 \gamma_2)^{-1} \gamma_1 (y_{1t} y_{2t} + x_{1t}' \beta_2 + u_{2t}) + x_{1t}' \beta_1 + u_{1t} \right], \quad (125) \]

and (123) as

\[ y_{2t} = y_{2t}^{(1)} = (1 - \gamma_1 \gamma_2)^{-1} \left[ \gamma_1 (y_{1t} y_{2t} + x_{1t}' \beta_1 + u_{1t}) + x_{2t}' \beta_2 + u_{2t} \right] \quad \text{if} \quad y_{yt}^* > 0, \]

\[ = y_{2t}^{(0)} = x_{2t}' \beta_2 + u_{2t} \quad \text{if} \quad y_{yt}^* \leq 0. \quad (126) \]

Thus, the likelihood function of the model is

\[ L = \prod_0 \int_0 f(y_{yt}^*, y_{2t}^{(0)}) \, d y_{yt}^* \prod_1 f(y_{1t}, y_{2t}^{(1)}), \quad (127) \]

which is the same as (117).

11. Type 5: \( P(y_1 < 0, y_2) \cdot P(y_1 > 0, y_2) \)

11.1. Definition and estimation

The Type 5 Tobit model is obtained from the Type 4 model (116) by omitting the equation for \( y_{yt} \). One merely observes the sign of \( y_{yt}^* \). Thus, the
model is defined by
\[ y_{it}^* = x_{it}^* \beta_i + u_{it}, \]
\[ y_{2t}^* = x_{2t}^* \beta_2 + u_{2t}, \]
\[ y_{3t}^* = x_{3t}^* \beta_3 + u_{3t}, \]
\[ y_{2t} = y_{2t}^* \quad \text{if} \quad y_{it}^* > 0, \]
\[ = 0 \quad \text{if} \quad y_{it}^* \leq 0, \]
\[ y_{3t} = y_{3t}^* \quad \text{if} \quad y_{it}^* \leq 0, \]
\[ = 0 \quad \text{if} \quad y_{it}^* > 0, \quad i = 1, 2, \ldots, n, \]

where \( \{u_{it}, u_{2t}, u_{3t}\} \) are i.i.d. drawings from a trivariate normal distribution.

The likelihood function of the model is
\[
L = \prod_{0}^{\infty} f_3(y_{1t}^*, y_{3t}^*) \, d\, y_{1t}^* \cdot \prod_{1}^{\infty} f_2(y_{1t}^*, y_{2t}^*) \, d\, y_{1t}^*,
\]

where \( f_3 \) and \( f_2 \) are as defined in (117). Since this model is somewhat simpler than Type 4, the estimation methods I discussed in the preceding section apply to this model a fortiori. Hence, I will immediately go into the discussion of applications.

11.2. Lee (1978) and Lee and Trost (1978)

In Lee's (1978) model, \( y_{it}^* \) represents the logarithm of the wage rate of the \( i \)th worker in case he or she joins the union and \( y_{3t}^* \) represents the same in case he or she does not join the union. Whether or not the worker joins the union is determined by the sign of the variable
\[
y_{it}^* = y_{2t}^* - y_{3t}^* + \alpha + \eta_i.
\]

Since we observe only \( y_{it}^* \) if the worker joins the union and \( y_{3t}^* \) if the worker does not, the logarithm of the observed wage, denoted \( y_i \), is defined by
\[
y_i = y_{2t}^* \quad \text{if} \quad y_{it}^* > 0, \]
\[
= y_{3t}^* \quad \text{if} \quad y_{it}^* \leq 0.
\]
Lee assumes that $x_2$ and $x_3$ (the independent variables in the $y_2^*$ and $y_3^*$ equations) include the individual characteristics of firms and workers such as regional location, city size, education, experience, race, sex and health, whereas $z$ includes certain other individual characteristics and variables which represent the monetary and non-monetary costs of becoming a union member. Since $y_1^*$ is unobserved except for the sign, the variance of $y_1^*$ can be assumed to be unity without loss of generality.

Lee estimated his model by Heckman's two-step method applied separately to the $y_2^*$ and the $y_3^*$ equations. In Lee's model, simultaneity exists only in the $y_1^*$ equation and hence is ignored in the application of Heckman's two-step method. Amemiya's LS or GLS, which accounts for the simultaneity, will of course work for this model as well and the latter will yield more efficient estimates, though, of course, not as fully efficient as the MLE.

The model of Lee and Trost (1978) is identical to Lee's model above except that $y_c$ is defined simply as $z_i'A + v_i$ and does not depend on the difference $y_{2i}^* - y_{3i}^*$ as in Lee's model. Thus, there is no simultaneity in the Lee-Trost model. In their model, $y_2^*$ and $y_3^*$ represent annual expenditure on the housing owned and rented respectively, $x_2$ and $x_3$ include the age, race, sex of the family head, family size, income, city size, distance from center of city and the relative price index of housing, while $z$ includes all the independent variables above except the last. In estimation, Heckman's two-step estimates were obtained and then used to start the Newton-Raphson iteration.

11.3. Heckman (1978)

Heckman's model is a simultaneous equations model consisting of two equations,

$$y_{1i}^* = \gamma_1 y_{2i} + x_{1i}' \beta_1 + \delta_1 w_i + u_{1i},$$  \hspace{1cm} (132)

and

$$y_{2i} = \gamma_2 y_{1i} + x_{2i}' \beta_2 + \delta_2 w_i + u_{2i},$$  \hspace{1cm} (133)

where we observe $y_{2i}$, $x_{1i}$, $x_{2i}$, and $w_i$ defined by

$$w_i = 1 \quad \text{if} \quad y_{1i}^* > 0,$$

$$= 0 \quad \text{if} \quad y_{1i}^* \leq 0.$$  \hspace{1cm} (134)

There are no empirical results in this article, but the same model is estimated by Heckman (1976b), in which $y_{2i}^*$ represents the average income of black people in the $i$th state, $y_{1i}^*$ the unobservable sentiment toward blacks in the $i$th state, and $w_i = 1$ if an antidiscrimination law is instituted in the $i$th state.
Another possible application of the model is to the same problem to which Lee's article was addressed (though Lee's model seems more suitable for this problem). Then, $y_{2i}$ would represent the $i$th worker's wage (or earnings) for both union and non-union workers, and $y_{3i}^*$ would represent the $i$th worker's propensity to join a union. As I will discuss later in section 10.4, such an application was made by Schmidt and Strauss (1976) using a special case of Heckman's model.

When one solves (132) and (133) for $y_{1i}^*$, the solution should not depend upon $w_i$, for that would clearly lead to logical inconsistencies. Therefore, one must assume

$$y_1 \delta_2 + \delta_1 = 0,$$

in order for Heckman's model to be logically consistent. Using the above constraint, the reduced-form equations (though strictly speaking not a reduced form because of the presence of $w_i$) of the model can be written as

$$y_{3i}^* = x_i' \pi_1 + v_{1i},$$

and

$$y_{2i} = \delta_2 w_i + x_i' \pi_2 + v_{2i},$$

where one can assume $Vv_{1i} = 1$ without loss of generality. Thus Heckman's model is a special case of Type 5 with just a constant shift between $y_{2i}^*$ and $y_{3i}^*$ (i.e., $y_{2i}^* = x_i' \pi_2 + v_{2i}$ and $y_{3i}^* = \delta_2 + x_i' \pi_2 + v_{2i}$). Moreover, if $\delta_2 = 0$, it is a special case of Type 5 where $y_{2i}^* = y_{3i}^*$.

Let us compare Heckman's reduced-form model defined by (136) and (137) with Lee's model. Heckman's (136) is essentially the same as Lee's (130). Lee's (131) can be rewritten as

$$y_i = w_i (x_i' \beta_2 + u_{2i}) + (1 - w_i) (x_i' \beta_3 + u_{3i})$$

$$= x_i' \beta_3 + u_{3i} + w_i (x_i' \beta_2 + u_{2i} - x_i' \beta_3 - u_{3i}).$$

By comparing (137) and (138), we readily see that Heckman's reduced-form model is a special case of Lee's model in which the coefficient multiplied by $w_i$ is a constant.

Heckman proposed a sequential method of estimation for the structural parameters, which can be regarded as an extension of Heckman's simulta-

23 Constraints like (131) are often necessary in simultaneous-equations model involving binary or truncated variables, as was first noted by Amemiya (1974b). For an interesting unified approach to this problem, see Gourieroux, Laffont and Monfort (1980).
neous-equations two-step estimation discussed in section 9.3. His method consists of the following steps: (1) Estimate \( \pi_i \) by applying the probit MLE to (136). Denote the estimator \( \hat{\pi}_i \) and define \( \hat{F}_i = F(x'_i \hat{\pi}_i) \). (2) Insert (136) into (133), replace \( \pi_i \) with \( \hat{\pi}_i \) and \( w_i \) with \( \hat{F}_i \), and then estimate \( \gamma_2, \beta_2 \) and \( \delta_2 \) by least squares applied to (133). (3) Solve (132) for \( y_{2i} \), eliminate \( y_{1i}^* \) by (136), and then apply least squares to the resulting equation after replacing \( \pi_i \) by \( \hat{\pi}_i \) and \( w_i \) by \( \hat{F}_i \) to estimate \( \gamma_{1i}^{-1}, \gamma_{1i}^{-1}\beta_1 \) and \( \gamma_{1i}^{-1}\delta_1 \).

Amemiya (1978) derived the asymptotic variance–covariance matrix of Heckman's estimator defined above and showed that Amemiya's GLS (defined in section 9.4) applied to the model yields an asymptotically more efficient estimator in the special case of \( \delta_1 = \delta_2 = 0 \). As pointed out by Lee (1981), however, Amemiya's GLS can be also applied to the model with non-zero \( \delta \)'s as follows: (1) Estimate \( \hat{\pi}_i \) by the probit MLE \( \hat{\pi}_i \) applied to (136). (2) Estimate \( \delta_2 \) and \( \pi_2 \) by applying the instrumental variables method to (137) using \( \hat{F}_i \) as the instrument for \( w_i \). Denote these estimators as \( \hat{\delta}_2 \) and \( \hat{\pi}_2 \). (3) Derive the estimates of the structural parameters \( \gamma_1, \beta_1, \delta_1, \gamma_2, \beta_2 \) and \( \delta_2 \) from \( \hat{\pi}_1, \hat{\pi}_2 \) and \( \hat{\delta}_2 \) using the relationship between the reduced-form parameters and the structural parameters as well as the constraint (135) in the manner described in section 9.4. The resulting estimator can be shown to be asymptotically more efficient than Heckman's.

11.4. Schmidt and Strauss (1976) and related papers

Schmidt and Strauss studied the effect of unions on earnings and earnings on unions by the following model:

\[
P(w_i = 1|y_{2i}) = \mathcal{L}(x'_i \beta_1 + \gamma_1 y_{2i}), \tag{139}
\]

where \( \mathcal{L}(x) = (1 + e^{-x})^{-1} \), and

\[
f(y_{2i}|w_i) = N(x'_i \beta_2 + \gamma_2 w_i, \sigma^2). \tag{140}
\]

In this model, \( w_i = 1 \) if the \( i \)th worker is a union member, \( y_{2i} \), represents the \( i \)th worker's earnings, and \( x_i \) includes education, experience, race, sex, and regional dummies.

Eq. (140) can be written as a regression equation like (137), but, unlike (137), \( w_i \) is independent of the error term of the regression because (140) describes a conditional distribution. From (139) and (140) one can derive the marginal distribution of \( w_i \) as

\[
P(w_i = 1) = \mathcal{L}(x'_i \beta_1 + \sigma^{-2} \gamma_2 x'_i \beta_2 + 2^{-1} \sigma^{-2} \gamma_2^2). \tag{141}
\]

In the process of obtaining the above result, it becomes apparent that one must
have

\[ a^2 \gamma_1 = \gamma_2 \]  

(142)

in order for the model to be logically consistent because, unless (142) holds, \( y_{2i} \) will appear in the argument of \( \mathcal{L} \) in the right-hand side of (141).\(^{24}\) Note that (141) can be written in the form of (136) with \( u_{1i} \) following a logistic distribution. Hence, we conclude that the Schmidt–Strauss model is essentially a special case of Heckman’s model in which \( u_{1i} \) and \( u_{2i} \) are independent. As pointed out by Lee (1979), this independence considerably simplifies the estimation: assuming that \( x_i \) contains a constant term, the MLE of all the parameters can be obtained by applying LS to (140) and the logit MLE to (141) separately.

Warren and Strauss (1979) used the same model as above to study a related but different problem. In their study, \( w_i = 1 \) if the \( i \)th state has right-to-work legislation and \( y_{2i} \) represents the proportion of non-agricultural employment that is unionized. The constraint (142) was also ignored in this study.

Schmidt (1978) considered the same union and earnings problem using a model which is a slight generalization of the Schmidt–Strauss model. It can be interpreted as Heckman’s model in which (137) is generalized as

\[ y_{2i} = w_i \cdot z_i(\alpha + \pi_2) + u_{2i}. \]  

(143)

Note that this equation is between (137) and (138) in its degree of generality concerning the term multiplied by \( w_i \). While it is more general than Heckman’s model in this sense, it is more restrictive than Heckman’s in the more significant sense that Schmidt, like Schmidt and Strauss or Warren and Strauss, assumes independence between \( u_{1i} \) and \( u_{2i} \).

Another example of the Schmidt–Strauss model is the model of Ray (1981), in which \( w_i = 1 \) if non-tariff barriers existed in the \( i \)th industry (U.S. four-digit manufacturing industry), \( y_{2i} \) represents an average of tariffs within the \( i \)th industry, and \( x_i \) includes various industry characteristics.

11.5. Disequilibrium models

Disequilibrium models constitute an extensive area of research, in which numerous papers have been written. Some of the early econometric models are surveyed by Maddala and Nelson (1974). A more extensive and up-to-date survey is given by Quandt (1982). See, also, Hartley (1976) for a connection between a disequilibrium model and the Standard Tobit model. Here I will

\(^{24}\)This constraint was overlooked by Schmidt and Strauss (1976) and was noted by Olsen (1978b).
only mention two basic models first discussed in the pioneering work of Fair and Jaffe (1972).

The simplest disequilibrium model of Fair and Jaffe is a special case of the Type 5 model (128), in which \( y_{2i}^* \) is the quantity demanded in the \( i \)th period, \( y_{3i}^* \) is the quantity supplied in the \( i \)th period, and \( Y_i^* = y_{3i}^* - y_{2i}^* \). Thus, the actual quantity sold, which a researcher observes, is the minimum of supply and demand. The fact that the variance-covariance matrix of \( (Y_i^*, y_{2i}^*, y_{3i}^*) \) is only of rank 2 because of the linear relationship above does not essentially change the nature of the model because the likelihood function (129) involves only bivariate densities.

Another model considered by Fair and Jaffe adds a price equation to the above as

\[
y_{4i} = \gamma (y_{2i}^* - y_{3i}^*), \tag{144}
\]

where \( y_{4i} \) denotes a change in the price at the \( i \)th period. The likelihood function of this model can be written as \(^{25}\)

\[
L = \prod_{i=0}^{\infty} \int_{-\infty}^{0} f_1(y_{1i}^*, y_{3i}) f(y_{4i}) \, dy_{4i}^* \times \prod_{i=1}^{\infty} \int_{0}^{\infty} f_2(y_{1i}^*, y_{2i}) f(y_{4i}) \, dy_{4i}^*.
\tag{145}
\]

The form of the likelihood function does not change if one adds a normal error term to the right-hand side of (144). In either case, the model may be schematically characterized by

\[
P(y_{1} < 0, y_{3}, y_{4}) \cdot P(y_{1} > 0, y_{2}, y_{4}), \tag{146}
\]

which is a simple generalization of the Type 5 model.

11.6. Multivariate generalizations

By a multivariate generalization of Type 5, I mean a model in which \( y_{2i}^* \) and \( y_{3i}^* \) in (128) are vectors, whereas \( y_{1i}^* \) is a scalar variable whose sign is observed as before. Therefore, the Fair–Jaffe model with likelihood function characterized by (146) is an example of this type of model.

In Lee’s model (1977), the \( y_{2i}^* \) equation is split into two equations,

\[
C_{2i}^* = x_{2i}' \beta_2 + u_2, \tag{147}
\]

\(^{25}\)A more explicit expression for the likelihood function was obtained by Amemiya (1974a), who pointed out the incorrectness of the likelihood function originally given by Fair and Jaffe.
and

\[ T_{1i}^* = z_{1i}^* \alpha_2 + v_2, \quad (148) \]

where \( C_{1i}^* \) and \( T_{1i}^* \) denote the cost and the time incurred by the \( i \)th person travelling by a private mode of transportation and, similarly, the cost and the time of travelling by a public mode are specified as

\[ C_{3i}^* = x_{3i}^* \beta_3 + u_3, \quad (149) \]

and

\[ T_{3i}^* = z_{3i}^* \alpha_3 + v_3, \quad (150) \]

Lee assumes that \( C_{1i}^* \) and \( T_{1i}^* \) are observed if the \( i \)th person uses a private mode and \( C_{3i}^* \) and \( T_{3i}^* \) are observed if he or she uses a public mode. A private mode is used if \( u_1 > 0 \), where \( u_1 \) is given by

\[ y_{1i}^* = s_1 \delta_1 + \delta_2 T_{2i}^* + \delta_3 T_{3i}^* + \delta_4 \left( C_{3i}^* - C_{2i}^* \right) + \epsilon_1. \quad (151) \]

Lee estimated his model by the following sequential procedure: (1) Apply the probit MLE to (151) after replacing the starred variables with their respective right-hand sides. (2) Apply LS to each of the four equations (147) through (150) after adding to the right-hand side of each the estimated hazard from step (1). (3) Predict the dependent variables of the four equations (147) through (150) using the estimates obtained in step (2) above, insert the predictors into (151) and apply the probit MLE again. (4) Calculate the MLE by iteration starting from the estimates obtained at the end of the step (3).

Willis and Rosen (1979) studied earnings differentials between those who went to college and those who did not using a more elaborate model than that of Kenny, Lee, Maddala and Trost (1979), which I discussed in section 10.2. In the model of Kenny et al., \( \gamma_i^* \) (the desired years of college education, whose sign determines whether one attends college) is specified not to depend directly on \( y_{2i}^* \) and \( y_{3i}^* \) (the earnings of the college-goer and the non-college-goer, respectively). The first inclination of a researcher might be to hypothesize \( y_{1i}^* = y_{2i}^* - y_{3i}^* \). However, this would be an oversimplification because the decision to go to college should depend on the difference in expected life time earnings rather than current earnings.

Willis and Rosen solved this problem by developing a theory of the maximization of discounted, expected life-time earnings, which led to the
following model:

\[ I_{2i}^* = x_{2i}'\beta_2 + u_2, \quad (152) \]

\[ G_{2i}^* = z_{2i}'\alpha_2 + v_2, \quad (153) \]

\[ I_{3i}^* = x_{3i}'\beta_3 + u_3, \quad (154) \]

\[ G_{3i}^* = z_{3i}'\alpha_3 + v_3, \quad (155) \]

and

\[ R_i = s_i'\gamma + e_i, \quad i = 1, 2, \ldots, n, \quad (156) \]

where \( I_{2i}^* \) and \( G_{2i}^* \) denote the initial earnings (in logarithm) and the growth rate of earnings for the college-goer, \( I_{3i}^* \) and \( G_{3i}^* \) denote the same for the non-college-goer, and \( R_i \) denotes the discount rate. It is assumed that the \( i \)th person goes to college if \( y_{1i}^* > 0 \) where

\[ y_{1i}^* = I_{2i}^* - I_{3i}^* + \delta_0 + \delta_1 G_{2i}^* + \delta_2 G_{3i}^* + \delta_3 R_i, \quad (157) \]

and that the variables with subscript 2 are observed if \( y_{1i}^* > 0 \), those with subscript 3 are observed if \( y_{1i}^* \leq 0 \), and \( R_i \) is never observed. Thus, the model is formally identical to Lee's model (1977). Willis and Rosen used the same estimation method as Lee's method given above.

Borjas and Rosen (1980) used the same model as Willis and Rosen to study the earnings differential between those who changed jobs and those who did not within a certain period of observation.

### 11.7. Multi-response generalizations

In all the models we have considered so far in section 11, the sign of \( y_{1i}^* \) determined two basic categories of observations, such as union members versus non-union members, states with an anti-discrimination law versus those without, or college-goers versus non-college goers. By a multi-response generalization of Type 5, I mean a model in which observations are classified into more than two categories. I will devote most of this section to a discussion of Duncan (1980), who seems to be the first person to present a full discussion of estimation methods applicable to this type of model.

Duncan presents a model of joint determination of the location of a firm and its input–output vectors. A firm chooses the location for which profits are maximized, and only the input–output vector for the chosen location is observed. Let \( s_i(k) \) be the profit of the \( i \)th firm when it chooses location \( k \), \( i = 1, 2, \ldots, n \), and \( k = 1, 2, \ldots, K \), and let \( y_i(k) \) be the input–output vector for
the \(i\)th firm at the \(k\)th location. To simplify the analysis, I will subsequently assume \(y_i(k)\) is a scalar, for a generalization to the vector case is straightforward. It is assumed that

\[
s_i(k) = x_{ik}^{(1)} \beta + u_{ik},
\]

(158)

and

\[
y_i(k) = x_{ik}^{(2)} \beta + v_{ik},
\]

(159)

where \(x_{ik}^{(1)}\) and \(x_{ik}^{(2)}\) are vector functions of the input–output prices and economic theory dictates that the same \(\beta\) appears in both equations.\(^ {26}\) It is assumed that \((u_{i1}, u_{i2}, \ldots, u_{iK}, v_{i1}, v_{i2}, \ldots, v_{iK})\) is an i.i.d. drawing from a \(2K\)-variate normal distribution. Suppose \(s_i(k_i) > s_i(j)\) for any \(j \neq k_i\). Then, a researcher observes \(y_i(k_i)\) but does not observe \(y_i(j)\) for \(j \neq k_i\).

For the subsequent discussion it is useful to define \(K\) binary variables for each \(i\) by

\[
w_i(k) = \begin{cases} 1 & \text{if } i\text{th firm chooses } k\text{th location,} \\ 0 & \text{otherwise,} \end{cases}
\]

(160)

and define the vector \(w_i = [w_i(1), w_i(2), \ldots, w_i(K)]'\). Also define \(P_{ik} = P(w_i(k) = 1)\) and the vector \(P_i = (P_{i1}, P_{i2}, \ldots, P_{iK})'\).

There are many ways to write the likelihood function of the model, but perhaps the most illuminating way is to write it as

\[
L = \prod_i f[y_i(k_i)|w_i(k_i) = 1] P_{ik}.
\]

(161)

where \(k_i\) is the actual location the \(i\)th firm was observed to choose.

The estimation method proposed by Duncan can be outlined as follows: (1) Estimate the \(\beta\) that characterize \(f\) in (161) above by nonlinear WLS. (2) Estimate the \(\beta\) that characterize \(P\) in (161) above by the multi-response probit MLE using the nonlinear WLS iteration. (3) Choose the optimum linear combination of the two estimates of \(\beta\) obtained in steps (1) and (2). I will explain these steps in more detail below.

In order to describe step (1) explicitly, we must evaluate \(\mu_i = E[y_i(k_i)|w_i(k_i) = 1]\) and \(\sigma^2 = V[y_i(k_i)|w_i(k_i) = 1]\) as functions of \(\beta\) and the variances and covariances of the error terms of equations (158) and (159). These conditional

\(^{26}\)Eq. (158) is the maximized profit function and (159) is an input demand or output supply function obtained by differentiating (158) with respect to the own input or output price (Hotelling’s lemma). For convenience only one input or output has been assumed, so strictly speaking \(x_{ik}^{(1)}\) and \(x_{ik}^{(2)}\) are scalars.
moments can be obtained as follows. Define \( z_i(j) = s_i(k_i) - s_i(j) \) and the \((K - 1)\)-vector \( z_j = [z_i(1), \ldots, z_i(k_i - 1), z_i(k_i + 1), \ldots, z_i(K)]' \). To simplify the notation, write \( z_j \) as \( z \) omitting the subscript. Similarly, write \( y_i(k_i) \) as \( y \). Also, define \( R = \mathbb{E}(y - Ey)(z - Ez)'; \quad [\mathbb{E}(z - Ez)(z - Ez)']^{-1} \) and \( Q = Vy - RE(z - Ez)(y - Ey)' \). Then, we obtain*27

\[
\mu_i = \mathbb{E}(y|z > 0) = Ey + RE(z|z > 0) - REz, \tag{162}
\]

and

\[
\sigma_i^2 = V(y|z > 0) = RV(z|z > 0)R' + Q. \tag{163}
\]

The conditional moments of \( z \) appearing in the formulae above can be found in Amemiya (1974, p. 1002) as well as in Duncan (1980, p. 850). Finally, I can describe the nonlinear WLS iteration of step (1) above as follows: Estimate \( \sigma_i^2 \) by inserting the initial estimates (for example, those obtained by minimizing \(|y_i(k_i) - \mu_i|^2\) of the parameters into the right-hand side of (163) – call it \( \hat{\sigma}_i^2 \). Minimize

\[
\sum_i \hat{\sigma}_i^{-2} [y_i(k_i) - \mu_i]^2, \tag{164}
\]

with respect to the parameters that appear in the right-hand side of (162). Use these estimates to evaluate the right-hand side of (163) again to get another estimate of \( \hat{\sigma}_i^2 \). Repeat the process, to yield new estimates of \( \beta \).

Now, consider step (2). Define

\[
\Sigma_i = \mathbb{E}(w_i - P_i)(w_i - P_i)' = D_i - P_iP_i', \tag{165}
\]

where \( D_i \) is the \( K \times K \) diagonal matrix whose \( k \)th diagonal element is \( P_{ik} \). To perform the nonlinear WLS iteration, first, estimate \( \Sigma_i \) by inserting the initial estimates of the parameters into the right-hand side of (165) (denote the estimate thus obtained as \( \hat{\Sigma}_i \)) and, second, minimize

\[
\sum_i (w_i - P_i)'\hat{\Sigma}_i^{-1}(w_i - P_i), \tag{166}
\]

where the minus sign in the superscript denotes a generalized inverse, with respect to the parameters that characterize \( P_i \), and repeat the process until the estimates converge.

Finally, regarding step (3) above, if we denote the two estimates of \( \beta \) obtained by step (1) and (2) by \( \hat{\beta}_1 \) and \( \hat{\beta}_2 \), respectively, and their respective

---

* These two equations correspond to two equations in a proposition of Duncan (1980, p. 851). It seems that Duncan inadvertently omitted the last term from (162).
asymptotic variance–covariance matrices\(^{28}\) by \(V_1\) and \(V_2\), the optimal linear combination of the two estimates is given by 

\[
(V_1^{-1} + V_2^{-1})^{-1}V_1^{-1}\hat{\beta}_1 + (V_1^{-1} + V_2^{-1})^{-1}V_2^{-1}\hat{\beta}_2.
\]

This final estimator is asymptotically not fully efficient, however. To see this, suppose the regression coefficients of (158) and (159) differ: call them \(\beta_1\) and \(\beta_2\), say. Then, by a result of Amemiya (1976), we know that \(\hat{\beta}_1\) is an asymptotically efficient estimator of \(\beta_1\). However, as I have indicated in section 4.4, \(\hat{\beta}_2\) is not. So a weighted average of the two could not be asymptotically efficient.

Dubin and McFadden (1980) used a similar model to Duncan’s in their study of the joint determination of the choice of electric appliances and the consumption of electricity. In their model, \(s_i(k)\) may be interpreted as the utility of the \(i\)th family when they use the \(k\)th portfolio of appliances, and \(y_i(k)\) as the consumption of electricity for the \(i\)th person holding the \(k\)th portfolio. The estimation method is essentially similar to Duncan’s. The main difference is that Dubin and McFadden assume that the error terms of (158) and (159) are distributed as Type I extreme value distribution and hence the \(P\) part of (161) is multinomial logit [cf. Amemiya (1981, p. 1516)].
